A group of 791 patients with normal pregnancies was used to assign limits to the amniotic fluid index and maximum vertical pocket. Patients were considered normal if infant birth weight was between the 10th and 90th percentiles according to California standards,[14] no fetal anomalies were present, and the 5-minute Apgar score was >6. Patients with twins, diabetes, hypertension, bleeding, preterm labor, fetal anomalies, or ruptured membranes were excluded. Only patients with satisfactory obstetric dating were included; a certain and normal last menstrual period plus either a confirmatory pelvic examination before 12 weeks or a confirmatory ultrasonogram between 8 and 24 weeks were acceptable dating methods. The study was cross-sectional: a single examination of each patient was used.

Ultrasonographic examinations were performed with an Ultramark IV (ADR, Bothell, Wash.) with linear transducers (3.5 and 5 Mhz). The maximum-vertical-pocket depth was obtained by measuring the depth of the single deepest unobstructed amniotic fluid pocket visible with the transducer kept parallel to the patient's sagittal plane. The amniotic fluid index was calculated as the sum of the maximum-vertical-pockets obtained in each of four quadrants of the uterus, as previously described.[12] This technique is similar to that described by Phelan et al.[9] except that only amniotic fluid pockets completely clear of cord or extremities were measured. When amniotic fluid index values <100 mm were observed the average of three measurements was re-

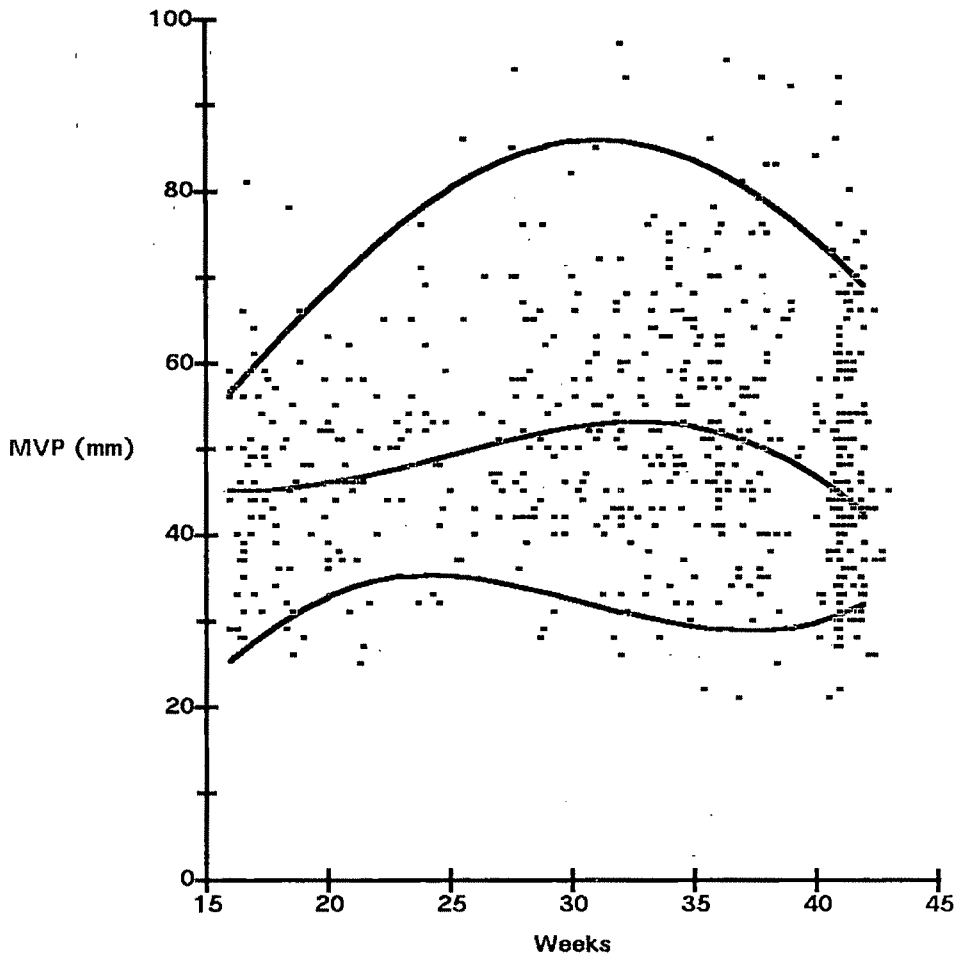

Fig. 2. Maximum-vertical-pocket *(MVP)* data points from normal patients plotted against gestational week. *Upper, middle, and lower* lines represent 95th, 50th, and 5th percentiles, respectively.

Table I. Oligohydramnios: uncorrected maximum-vertical-pocket technique versus amniotic fluid index

Maximum vertical pocket	*Amniotic fluid index*	
	Normal	*Oligohydramnios**
Normal†	1010	44
Oligohydramnios‡	31	32

*Patients whose amniotic fluid index was <5th percentile.
†Patients whose maximum vertical pocket was ≥3 cm.
‡Patients whose maximum vertical pocket was <3 cm.

Table II. Polyhydramnios: uncorrected maximum-vertical-pocket technique versus amniotic fluid index

Maximum vertical pocket	*Amniotic fluid index*	
	Normal	*Polyhydramnios**
Normal†	1026	29
Polyhydramnios‡	15	22

*Patients whose amniotic fluid index was >95th percentile.
†Patients whose maximum vertical pocket was ≤8 cm.
‡Patients whose maximum vertical pocket was >8 cm.

corded to minimize the intraobserver variation encountered with relative oligohydramnios.[12, 15]

The data from the amniotic fluid index observations in the normal patient group were not normally distributed. Logarithmic transforms were used to normalize the variance in each gestational period before analysis. The mean and standard deviation of the log amniotic fluid index was calculated for each week of gestation. A 90% confidence interval (5th to 95th percentiles) was chosen to define "normal." The critical value for oli-

gohydramnios was defined as the 5th percentile. The critical value for polyhydramnios was defined as the 95th percentile. The critical values for abnormal amniotic fluid index were then calculated from the data base stratified by gestational week.

Critical values for the maximum-vertical-pocket were assigned similarly. First, pan-gestation maximum-vertical-pocket values were determined as proposed by Chamberlain et al.[5] by calculating the mean and standard deviation of the maximum-vertical-pocket observations from the entire sample. The 1st (20 mm), 5th (30 mm), 95th (80 mm), and 99th percentiles (93 mm) were computed (uncorrected values). Second, the data set was stratified by pregnancy week and critical values (5th and 95th percentiles) were assigned by gestational age (corrected values).

Fig. 1 illustrates the critical values (5th and 95th percentiles) for the amniotic fluid index from 16 to 42 weeks determined from the normal patient group. Two-way analysis of variance demonstrated a highly statistically significant variation in normal amniotic fluid index values from week to week during gestation ($F = 4.22$, $p < 0.00001$). Fig. 2 depicts the 5th, 50th, and 95th percentiles for the maximum-vertical-pocket in normal patients. Analysis of variance resulted in a weakly significant variation in mean maximum vertical pocket across gestation ($F = 2.2$, $p < 0.05$) but no two gestational segments were statistically distinct (Bonferroni test for multiple comparisons, $p > 0.05$).

The critical values (5th and 95th percentiles) of the amniotic fluid index and maximum-vertical-pocket were then applied to a separate high-risk population of 1178 patients scanned for a variety of indications. Because the amniotic fluid index has been shown to be linearly proportionate to amniotic fluid volume,[11] the amniotic fluid index was used as the volume standard against which the maximum-vertical-pocket criteria were compared. Statistical analysis was performed with a computer-based software package (SPSS), using two-tailed analyses with probability values <0.05 considered significant.

Results

A total of 76 patients (7%) in the test population had oligohydramnios as defined by the amniotic fluid index. The efficiency of the maximum-vertical-pocket technique (uncorrected limit, 30 mm) in correctly detecting oligohydramnios is presented in Table I. Only 32 (42%) of patients with oligohydramnios were correctly identified, whereas 31 patients with normal fluid were incorrectly diagnosed as having decreased amniotic volume. The results among the 51 patients with polyhydramnios were similar (Table II). True-positive diagnoses occurred in 22, whereas 15 normal patients were incorrectly identified as having excessive amniotic fluid.

Table III. Sensitivity and specificity of maximum-vertical-pocket technique in detecting oligohydramnios and polyhydramnios as defined by abnormal amniotic fluid index

Maximum vertical pocket	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*False-positive rate (%)*
<1 cm	5	100	100	95
<3 cm	42	97	51	58
<5th percentile	43	97	52	57
>8 cm	43	99	59	57
>95th percentile	49	98	41	51

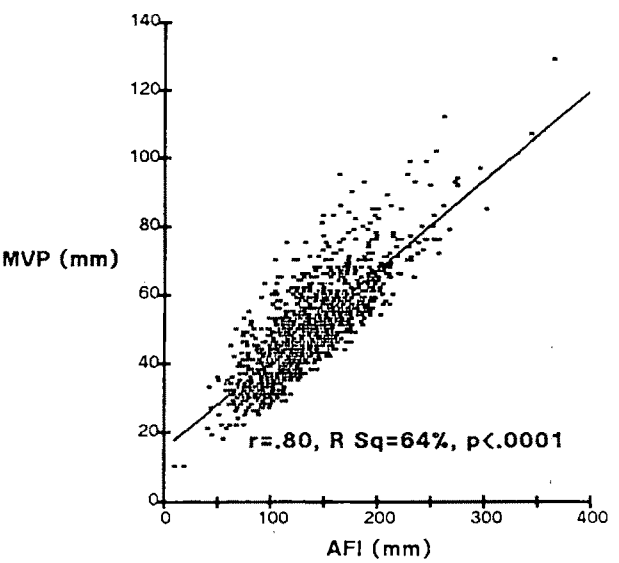

Fig. 3. Amniotic fluid index *(AFI)* and corresponding maximum-vertical-pocket *(MVP)* values compared (high-risk patients).

The sensitivity, specificity, and predictive values of the maximum-vertical-pocket criteria in detecting abnormal amniotic fluid volumes are shown in Table III. Use of a single limit (30 mm) for the maximum-vertical-pocket at all gestations resulted in a sensitivity for detection of oligohydramnios of only 42%. Narrowing the definition of oligohydramnios to the "1 cm rule" lowered sensitivity to 5%. Use of gestation-corrected values for maximum-vertical-pocket (percentiles) did not significantly improve the sensitivity (43% to 49%) and low

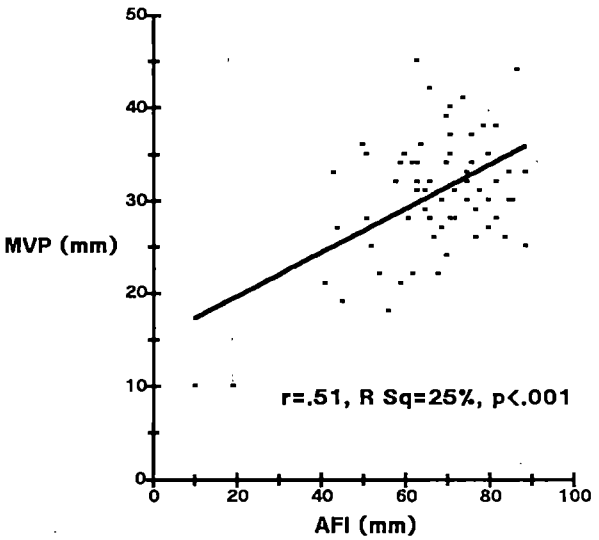

Fig. 4. Amniotic fluid index and maximum-vertical-pocket *(MVP)* values in patients with oligohydramnios (high-risk patients).

positive predictive values. However, the specificity of all maximum-vertical-pocket criteria was uniformly high (97% to 100%).

Fig. 3 shows the relationship of the amniotic fluid index and maximum-vertical-pocket in the test population. The linear correlation is statistically significant, but the regression curve explains only 64% of the variance. Splay from the regression line is marked at the lower (amniotic fluid index < 75 mm) and upper (amniotic fluid index > 250 mm) ends of the range. In patients with oligohydramnios (Fig. 4), the correlation coefficient relating amniotic fluid index and maximum vertical pocket was especially poor ($r = 0.51$).

Comment

Effective use of amniotic fluid volume assessment in monitoring high-risk pregnancy depends on the accuracy of the measures used. Both the single-pocket technique and the four-quadrant methods have been shown to correlate well with neonatal outcome.[1, 5, 6, 9, 10, 16-18] However, this study addressed the issue of accuracy of volume quantitation. The accuracy of single amniotic fluid pocket measurement was compared with the four-quadrant technique, which has been shown to predict volume accurately in the laboratory.[11]

The widely used maximum-vertical-pocket technique has the advantage of ease of use, but this study indicates that currently recommended standards for the maximum-vertical-pocket (2 and 8 cm "rules") are insufficiently sensitive for ultrasonographic screening of amniotic fluid volume. Even when the critical maximum-vertical-pocket values were adjusted for gestational age, the maximum-vertical-pocket sensitivity for oligohydramnios and polyhydramnios was below 50%. Moreover, false-positive diagnoses among patients with normal amniotic fluid approached 50%. These findings confirm those of Bottoms et al.[8] and Rutherford et al.[10]

The inaccuracy of a single-pocket measurement in assessment of amniotic fluid volume is emphasized in patients with oligohydramnios. In this group the correlation between maximum-vertical-pocket and amniotic fluid index was poor. Hoddick et al.[7] reported similarly low sensitivity in detection of intrauterine growth retardation in patients with oligohydramnios whereas Rutherford et al.[10] demonstrated that the amniotic fluid index offers more reliability and sensitivity in this important group of patients.

Ideally, these studies should be performed with controlled volume infusions into the amniotic space of human subjects. Until studies that correlate ultrasonographic measurements of fluid pockets and actual amniotic fluid volume in human pregnancy are available, the amniotic fluid index currently provides the most accurate and reliable method of screening for amniotic fluid volume abnormalities.

I thank Jon Cayle, MD, for his assistance in data entry and continued interest in this project.

Randomized investigation of magnesium sulfate for prevention of preterm birth

Susan M. Cox, MD, M. Lynne Sherman, RN, and Kenneth J. Leveno, MD
Dallas, Texas

One hundred fifty-six women with preterm labor between 24 and 34 weeks' gestation were randomized to receive either intravenous magnesium sulfate or no tocolytic therapy. Magnesuim sulfate infusions of up to 3 gm/hr were used in 76 pregnancies and resulted in a mean serum magnesium concentration of 5.5 ± 1.4 mEq/L (mean ± SEM). Compared with 80 control pregnancies, magnesium sulfate tocolysis had no significant effect on duration of gestation, birth weight, neonatal morbidity, and perinatal mortality. We conclude that clinically safe infusions of magnesium sulfate are ineffective when used to prevent preterm birth. (AM J OBSTET GYNECOL 1990;163:767-72.)

Key words: Magnesium sulfate, preterm labor

Effective methods for treatment of preterm labor have become major goals in modern obstetrics because preterm birth is the leading cause of infant morbidity and mortality. A significant cause of preterm birth, labor without ruptured membranes or other obstetric complications necessitating intervention, has been the focus of several pharmacologic approaches aimed at inhibition of uterine contractions. Agents that were used include ethanol,[1-4] prostaglandin synthetase inhibitors,[2, 5, 6] various β-adrenergic sympathomimetics,[7-13] calcium channel blockers,[14] and magnesium sulfate.[11-13, 15-17]

Side effects and clinical conditions that contraindicate the use of β-sympathomimetics have recently directed the focus of attention to the use of magnesium sulfate for the inhibition of preterm labor because high concentrations of magnesium ion inhibit uterine contractility. Specifically, concentrations of 8 to 10 mEq/L were observed to reduce the frequency of in vitro uterine muscle contraction, whereas magnesium levels of 20 mEq/L were necessary for complete cessation of activity.[18] Several studies[11-13, 15-17] have suggested that magnesium sulfate is a reasonably safe and effective agent for tocolysis, although no large randomized investigations comparing this therapy with untreated controls have been reported. We sought to determine if clinically safe magnesium concentrations (i.e., those <8 mEq/L, at which level skeletal muscle paralysis occurs) were effective in preventing preterm birth when compared with untreated controls.

Material and methods

Subjects for study were from the population of women who came to the obstetrics service at Parkland Memorial Hospital in Dallas between October 1987 and May 1989. Criteria for enrollment included: (1) preterm labor defined by regular uterine contractions as-

sociated with cervical dilatation of at least 1 cm but <5 cm, (2) gestational age between 24 and 34 weeks; (3) intact fetal membranes, and (4) no maternal or fetal complications necessitating delivery. Women who fulfilled these criteria were asked to participate and those who gave informed written consent were enrolled in the investigation, which was performed under the auspices of the Institutional Review Board on Human Research for the University of Texas Southwestern Medical Center at Dallas and Parkland Memorial Hospital. The use of magnesium sulfate for tocolysis at our hospital was restricted to this investigation.

Patients were assigned to treatment or control groups by means of a random number table with group allocation predetermined and placed in consecutively numbered and sealed envelopes. Those randomized to the treatment group received 4 gm of magnesium sulfate in a 20% solution as an intravenous loading dose followed by an infusion of 2 gm/hr. The infusion rate was increased to 3 gm/hr if uterine contractions persisted 1 hour after commencement of therapy. Intravenous magnesium sulfate was continued for 24 hours and no other drug therapy was used during or subsequent to these infusions. Women with recurrent preterm labor at a later date were eligible for a second treatment with intravenous magnesium sulfate. Women assigned to the control group received intravenous physiologic saline solution at a rate of 80 ml/hr for 24 hours.

All women enrolled in the study had continuous electronic fetal heart rate monitoring for 12 to 24 hours and were observed in the labor suite for a minimum of 24 hours. All women who were undelivered in both groups were hospitalized until 34 weeks' gestation in the antepartum pregnancy unit. Laboratory tests for all women included real-time ultrasonographic examination, urinalysis, hematocrit, serum creatinine, glucose, and electrolyte studies. Magnesium level determinations were repeated serially in women randomized to this treatment group.

Therapy was considered unsuccessful if the fetal

membranes ruptured, cervical dilatation progressed to >4 cm, contractions persisted longer than 30 minutes at the maximum magnesium dose with continued cervical dilatation, or maternal side effects necessitated discontinuation of the drug. Maternal side effects such as muscle weakness and symptomatic hypotension prompted a reduction in magnesium dose. If a progressive reduction in dosage was ineffective in relief of these symptoms, or if maternal respiratory depression was noted, use of magnesium sulfate was discontinued.

Entry characteristics and outcome variables were analyzed with Student's t test, χ^2 analysis, or Fisher's exact test of probability. Results in which the probability of a type 1 error were <0.05 were considered significant.

Results

A total of 156 pregnancies were included during the 19-month study; 76 were randomized to receive magnesium sulfate and 80 to the control group. The clinical characteristics of the two study groups are shown in Table I. There were no significant differences between the two groups with respect to maternal age, parity, or racial composition. Similarly, there was no significant difference in the incidence of prior preterm birth defined as birth weight <2500 gm. Table II shows gestational age, cervical dilatation, and effacement at entry into the study for pregnancies randomized to receive magnesium sulfate compared with controls. There were no significant differences in any of these study entry characteristics.

Table III summarizes selected pregnancy outcomes including gestational age at delivery and days gained in utero. Significantly fewer pregnancies randomized to magnesium sulfate were delivered between 33 and 35 weeks' gestation ($p = 0.02$) compared with the control group. However, all other comparisons were not significant, including rates of cesarean section, which were 16.4% and 17.8%, respectively, for magnesium sulfate and control groups.

Selected neonatal outcomes according to maternal treatment group are summarized in Table IV. Results in pregnancies randomized to receive magnesium sulfate did not differ significantly from the control group with respect to birth weight, 5-minute Apgar scores, or number of days of neonatal intensive care. Similarly, indices of serious neonatal morbidity, such as respiratory distress, intracranial hemorrhage, and necrotizing enterocolitis, were not affected by preterm labor management. Two intrapartum fetal deaths occurred in pregnancies randomized to magnesium sulfate; one resulted from abruptio placentae several weeks after tocolytic therapy, and multiple anomalies were present in the other stillbirth. As shown in Table V, there were a total of six neonatal deaths; 5 occurred in the magnesium sulfate group. Factors implicated in these deaths included complications of immaturity ($n = 4$) and congenital malformations ($n = 2$). One death occurred in each treatment group after 28 days of life but before discharge.

Of the 76 women randomized to receive magnesium sulfate, 62% received the maximum dose of 3 gm/hr. The mean serum magnesium concentration in the treatment group was 5.5 ± 1.4 (SEM) mEq/L. This value reflects the mean of at least three measurements per pregnancy at the maximum magnesium sulfate infusion rates. Magnesium infusions were discontinued in eight women (11%) because of toxicity that included generalized muscle weakness ($n = 6$), respiratory depression ($n = 1$), and systemic hypotension ($n = 1$).

Comment

Side effects, in addition to the clinical conditions that contraindicate the use of β-sympathomimetics, have

served to focus attention on the use of magnesium sulfate given intravenously as an alternative tocolytic drug. In 1959 Hall et al.[18] demonstrated that strips of human gravid uterine muscle had reduced contractility in the presence of magnesium ion. Specifically, concentrations of magnesium approximating 8 to 10 mEq/L were observed to reduce the frequency of in vitro uterine muscle contractions. Complete inhibition of uterine activity, however, required magnesium concentrations of approximately 20 mEq/L. Other investigators have shown in humans that concentrations of 8 to 10 mEq/L result in loss of patellar reflexes with respiratory depression occurring at 10 mEq/L and respiratory arrest at 12 mEq/L or higher concentrations.[19]

The first centers in the United States to use magnesium for tocolysis were the Columbia-Presbyterian Medical Center, where the drug has been used routinely since 1969, and the University of Virginia, where it has been used since 1970.[16] In 1977 Steer and Petrie[15] evaluated intravenous magnesium sulfate given for to-

colytic therapy to 31 women for preterm labor and found such therapy effective in stopping uterine contractions for at least 24 hours. The magnesium sulfate dosage was 4 gm of a 10% solution followed by 2 gm/hr. Spisso et al.[17] subsequently also reported use of magnesium sulfate to be effective in delaying delivery 48 hours or longer in a nonrandomized study that included 119 pregnancies with preterm labor and intact fetal membranes.

In a retrospective study Elliott[20] reported successful use of magnesium sulfate for inhibition of preterm labor in 274 pregnancies. Magnesium sulfate was infused in dosages of up to 3 mg/hr with serum magnesium concentrations that ranged as high as 10 mEq/L. The frequency of such toxic levels and the consequences were not specifically cited, although Elliott concluded that the side effects of magnesium infusions compared favorably with those reported for β-sympathomimetics. He also observed empirically that magnesium serum levels of approximately 4 to 6 mEq/L were usually sufficient to inhibit uterine contractions. More recently Hollander et al.[13] evaluated the use of magnesium sulfate as a tocolytic agent with even higher dosages. In their study the efficacy of magnesium sulfate was analyzed in relation to ritodrine hydrochloride. The mean magnesium sulfate dosage required to achieve tocolysis was reported to be 4.5 gm/hr and the mean magnesium level resulting in tocolysis was 6.6 mg/dl (5.3 mEq/L). The dosage regimen used in this investigation included a 4 gm bolus injection of magnesium sulfate followed by 2 gm/hr intravenously. The infusion rate was increased at 30-minute intervals by 1 gm/hr and to a maximum infusion of 5 gm/hr. After successful tocolysis the infusion rate was decreased to the lowest effective rate required to maintain uterine quiescence and also maintain serum magnesium levels in the range of 6 to 8 mg/dl. Such infusions were then continued for a period of 12 hours. Among 33 women who were treated only with magnesium sulfate, the reported regimen necessitated a decrease in dosage because of lethargy in 15 women (45%). The experience of these investigators suggests that effective uterine contraction–inhibiting concentrations of magnesium must be near toxic levels to anticipate a clinical uterine effect. The margin between safety and efficacy of magnesium sulfate infusions for tocolysis appears to be quite narrow.

To date, there has been only one published randomized investigation in which magnesium sulfate tocolysis was compared with untreated controls.[11] Cotton et al. randomized a total of 54 women with preterm labor between 26 and 34 weeks' gestation to treatment with magnesum sulfate, placebo, or terbutaline. They defined successful tocolysis as postponement of delivery for at least 48 hours. Patients assigned to the magnesium sulfate group (n = 16) received 4 gm intravenously over 15 minutes and then a continuous infusion of 2 gm/hr. They found no significant differences among the three treatment groups with regard to delay of delivery 48 hours or longer.

Our study was prompted because magnesium sulfate is frequently used as a tocolytic agent but has not been studied extensively with randomization and untreated control subjects. During the study period 23,658 women were delivered at our hospital. On the basis of a previous survey of low birth weight at our hospital, we estimate that a maximum of 294 (1.3%) pregnancies were eligible for randomization during this investigation. However, patients commonly declined randomization and clinical developments before written consent could be obtained frequently excluded potential patients. It is important to note that women who met the study inclusion criteria were consistently offered participation in this investigation. Indeed, 156 randomized pregnancies may seem like a small number; however, this population represents the largest single center randomized study to compare a tocolytic drug with no treatment.

We elected to use modest infusion rates of magnesium sulfate to avoid the unacceptably high incidence of toxicity reported with infusion rates in excess of 3 gm/hr. The majority (62%) of the women received infusions of 3 gm/hr and achieved serum magnesium concentrations well within the range of values previously reported to be effective for inhibition of preterm uterine contractions. Specifically, the maximum magnesium concentration in this study was 5.5 ± 1.4 mEq/L (mean ± SEM); this level compares favorably with the results of Elliott[20] (4 to 6 mEq/L) and Hollander et al.[13] (6.6 mg/dl, equivalent to 5.3 mEq/L). We believe that magnesium ion in sufficient concentrations can inhibit muscle activity, including the uterus, but found that concentrations less than these levels do not effectively delay delivery in women with pregnancies complicated by preterm labor. Moreover, we were unable to document any perinatal benefit when magnesium sulfate infusions were used to prevent preterm birth compared with untreated control subjects. We therefore conclude that magnesium sulfate infusions resulting in maximum serum concentrations of magnesium equal to 5.5 mEq/L are ineffective in the prevention of preterm birth.

Fetal gastroschisis and omphalocele: Is cesarean section the best mode of delivery?

David F. Lewis, MD, Craig V. Towers, MD, Thomas J. Garite, MD, David N. Jackson, MD, Michael P. Nageotte, MD, and Carol A. Major, MD

Orange, Long Beach, and Pasadena, California

There has always been controversy regarding the mode of delivery of fetuses with abdominal wall defects. Prior studies may have been biased in this evaluation as a result of the effects of delay in repair, transport of the fetus to level III facilities, and antenatal diagnosis compared with an unsuspected diagnosis. The purpose of this study was to evaluate mode of delivery at level III institutions with access to complete care to determine if cesarean section improved outcome. One hundred eight infants were treated in the study period for abdominal wall defects. Fifty-six infants met all criteria for admission to the study. No difference in neonatal morbidity or mortality was identified. No difference was found in infants who were born by elective cesarean section compared with infants delivered after labor ensued. In conclusion, we found no evidence that cesarean section or avoidance of labor improved outcome in fetuses with uncomplicated abdominal wall defects. (AM J OBSTET GYNECOL 1990;163:773-5.)

Key words: Gastroschisis, omphalocele, mode of delivery

The accuracy of prenatal diagnosis of many congenital abnormalities has been dramatically improved with advances in high-resolution ultrasonography. With an increasing frequency of antenatal diagnosis of certain fetal abnormalities, planning appropriate management has become an area of much research. Frequently there is no clear consensus for management of specific fetal malformations.

This problem exists with respect to the most appropriate mode of delivery of infants with gastroschisis or omphalocele. Several authors have found no difference between vaginal and abdominal delivery.[1-5] Others have reported that cesarean delivery decreases both neonatal morbidity and mortality.[3, 7] All previous studies, however, suffer from the presence of multiple confounding variables.[8]

The purpose of this study was to evaluate route of delivery on outcome in infants with gastroschisis or omphalocele while eliminating significant confounding variables.

Material and methods

The charts of all infants treated for either omphalocele or gastroschisis, as defined by Moore and Stokes[9], between January 1984 through October 1989 were reviewed. Three level III institutions were the source of the patient population: the University of California at Irvine Medical Center, Long Beach Memorial Womens Hospital, and Huntington Memorial Hospital of Pasadena. Patients were excluded if they were transported after delivery from other institutions, or had multiple congenital anomalies, chromosomal abnormalities, or an extracorporeal liver.

The following factors were statistically analyzed: antenatal diagnosis, estimated gestational age at delivery, route of delivery, mean birth weight, delay in repair of the defect after birth, neonatal length of stay, 5-minute Apgar scores, and neonatal mortality.

Table II. Comparison by delivery mode

Factor	*Vaginal delivery (N = 23)*	*Cesarean section (N = 33)*
Antenatal diagnosis	10	23*
Omphaloceles	4	4
Gestational age (wk)	36.3 ± 3.2	36.0 ± 3.1
Birth weight (gm)	2554 ± 897	2608 ± 623
Delay in surgery (hr)	6.34 ± 4.5	5.24 ± 4.7
Neonatal length of stay of survivors (days)	28.24 ± 24.7	35.2 ± 27.1
5 Min Apgar score	8.6 ± 0.6	8.6 ± 0.8
Mortality	1	3

Values are represented as mean ± SD.

Necrotizing enterocolitis	3	4
Meconium aspiration	0	3
Sepsis	2	3
Respiratory distress syndrome	2	3
Staged closure	7	7

Table IV. Comparison of patients with elective cesarean sections with patients who entered labor

Factor	*Elective cesarean section (N = 23)*	*Labor (N = 33)*
Antenatal diagnosis	23	15
Omphalocele	3	5
Birth weight (gm)	2648 (575)	2543 (842)
Gestational age (wk)	36.1 (1.4)	36.2 (3.2)
Neonatal length of stay of survivors (days)	35.2 (31.2)	30.1 (24.6)
Mortality	3	1

Data are represented as mean ± SD.

Two groups were established to determine if labor adversely affects infants with abdominal wall defects: those infants delivered after labor had begun (i.e., the vaginal group and those delivered by cesarean section after labor ensued) and those delivered by elective cesarean section. The same parameters were statistically analyzed between those patients delivered by cesarean section with or without labor.

Statistical analysis was performed with the Student *t* test.

Results

One hundred eight infants were treated for gastroschisis or omphalocele during the study interval. Fifty-two patients were excluded from the study because they did not meet criteria (Table I). Fifty-six met all criteria for study evaluation. There were no differences in gestational age at delivery, birth weight, Apgar score at 5 minutes, neonatal length of stay, or delay in surgical repair of the defect between patients delivered vaginally and those delivered by cesarean section (Table II). However, antenatal diagnosis was found to be more frequent in patients delivered by cesarean section ($p < 0.02$). All patients delivered by elective cesarean section had the noted defect as one of the indications for cesarean delivery. In addition, five of the infants were breech, three mothers had previous cesarean sections, and one had pregnancy-induced hypertension. No difference in neonatal morbidity or mortality was identified between the groups. There were no significant differences in neonatal complications between the groups (Table III). Further analysis of patients delivered with or without labor failed to reveal any differences (Table IV). Labor did not influence outcome. There were no differences in outcome between institutions, and neonatal outcome was the same with either gastroschisis or omphalocele as the fetal abnormality. Infants who were delivered closer to term (>34 weeks) were also separately evaluated and no differences were found.

Comment

As the ability to diagnose congenital abnormalities has improved, questions of management, intervention, and ethics are being encountered. Frequently, these questions are difficult to resolve when counseling a family with a specific fetal abnormality. The optimal route of delivery for patients with fetal abdominal wall defects is one such difficult area. Previous studies on mode of delivery of these infants have been potentially biased in several ways. These biases include delivery of the infant at a level I or II facility with subsequent transport to a level III institution, delay in surgical repair, and appropriate neonatal resuscitation capability. Consequently, interpretation of outcome data may be misleading. In this study we analyzed infants with gastroschisis or omphalocele delivered in an optimal environment for resuscitation and repair and compared vaginal delivery with cesarean section to de-

termine whether delivery mode affected neonatal outcome.

All study participants were delivered in a level III institution with readily available perinatologist, neonatologist, and pediatric surgeon. Infants with lethal congenital malformations, chromosomal abnormalities, or extracorporeal livers were excluded. Although studies do not exist with regard to infants with extracorporeal livers, we thought that this factor could significantly alter the data. There were only four cases in our study with extracorporeal livers that did not also have a chromosomal abnormality or other multiple anomalies. Inclusion of these four cases did not result in significant differences in outcome.

A randomized prospective study would be the best method to determine whether mode of delivery affects outcome in infants with abdominal wall defects. However, the above confounding variables should be assessed if such a study is performed.[7,8]

When the mode of delivery of a fetus with a structural abnormality is evaluated, the possibility exists that labor itself may have an adverse affect on outcome. Therefore we evaluated the cesarean section group by comparison of those with labor and those without labor; no difference in fetal outcome was observed. Even when all cases with labor (vaginal delivery and cesarean section) were compared with elective cesarean section without labor, no differences occurred.

In this study no benefit could be established for elective abdominal delivery. There was no difference in morbidity, mortality, length of stay of surviving infants, or overall outcome between the vaginal delivery group and the cesarean section group. Therefore cesarean section in the management of fetal abdominal wall defects should be reserved for obstetric indications only. To achieve the best possible outcome these infants should be delivered in a level III institution with good communication between the perinatal and neonatal teams.

We thank Bharat Shah, MD, for providing information from Huntington Memorial Hospital of Pasadena.

Acute fetal hemodynamic alterations after intrauterine transfusion for treatment of severe red blood cell alloimmunization

Kenneth J. Moise, Jr., MD,[a] Giancarlo Mari, MD,[a] David J. Fisher, MD,[b] James C. Huhta, MD,[c] Lorraine E. Cano, RN,[a] and Robert J. Carpenter, Jr., MD[a]

Houston, Texas, and Philadelphia, Pennsylvania

One of the compensatory hemodynamic mechanisms seen in the anemic human fetus is an increased cardiac output. With Doppler techniques, cardiac output was measured in 21 fetuses before and immediately after 38 intrauterine transfusions for severe red cell alloimmunization. Umbilical venous pressures were measured before and after transfusion; amniotic fluid pressure was also quantitated. After subtraction of amniotic pressure, umbilical venous pressure increased by 1.7 ± 2.8 mm Hg ($p < 0.01$). Left and right ventricular output declined by 19% and 22%, respectively ($p < 0.001$). Four factors are known to affect cardiac output: heart rate, cardiac contractility, preload, and afterload. Fetal heart rate and mean acceleration, a measure of myocardial contractility, were unchanged after transfusion. A calculated mean increase in the fetoplacental volume of 18% in conjunction with an increase in umbilical venous pressure would indicate that cardiac preload was increased. We propose that intravascular intrauterine transfusion leads to an increased cardiac afterload, possibly by increasing blood viscosity. The fetal heart responds to the increased afterload by a decrease in stroke volume, leading to a fall in cardiac output. (Am J Obstet Gynecol 1990;163:776-84.)

Key words: Red cell alloimmunization, intrauterine transfusion, umbilical venous pressure, fetal cardiac output

Red cell alloimmunization results in the progressive destruction of fetal red cells, eventually leading to fetal anemia and hydrops. Compensatory mechanisms by which the fetus responds to this anemia include an increase in cardiac output and alterations in regional blood flow.[1, 2] Although these mechanisms have been studied in the animal fetus with the acute induction and correction of anemia, human studies have been limited to date.

Doppler techniques have been used to study blood flows in the human fetus in a noninvasive fashion. Blood velocities in the descending aorta of anemic fetuses have been found to be higher than those in controls.[3] Other investigators have reported increased umbilical venous flow in the fetus with anemia.[4] These findings are suggestive that the human fetus, like animal models, may respond to anemia with an elevation in cardiac output. With Doppler ultrasonography, Copel et al.[5] reported that cardiac output in anemic fetuses is higher than in control fetuses matched for gestational age. However, these authors could not demonstrate any change in cardiac output 24 hours after correction of anemia by direct intravascular transfusion.[6]

In two reports,[7, 8] an increase in human fetal umbilical venous pressure was detected after intravascular transfusion for red cell alloimmunization. An increase in the fetal blood volume as a result of the intravascular transfusion could not be correlated with the increased umbilical venous pressure. However, Nicolini et al.[7] were able to find that an increase in fetal hematocrit correlated with a rise in umbilical venous pressure.

We postulated that acute alterations in fetal cardiac output may occur in the human fetus soon after correction of anemia. There are four determinants of cardiac output: heart rate, cardiac contractility, preload, and afterload.[9] To better understand the cardiovascular responses to transfusion in the human fetus, we measured cardiac output and assessed its determinants before and after intravascular transfusions for red cell alloimmunization.

Material and methods

The study protocol was approved by the human investigational review boards of Baylor College of Medicine, St. Luke's Episcopal Hospital, and the Harris County Hospital District.

The study population comprised 21 fetuses under-

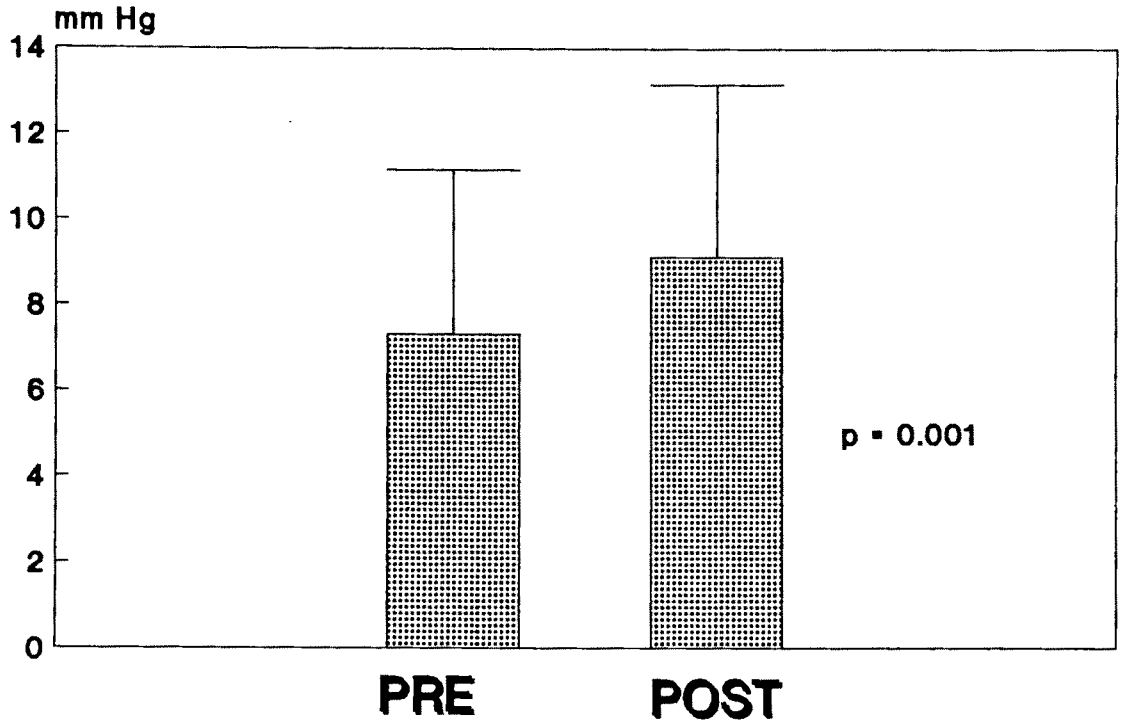

Fig. 1. Corrected umbilical venous pressure before and after transfusion (mean ± SD).

going 38 intravascular transfusions. One pregnancy involved Kell alloimmunization, one involved little "c" disease, and the remaining 19 pregnancies were complicated by anti-D alloimmunization. The number of procedures during which hemodynamic studies were undertaken was as follows: 1 transfusion, 11 fetuses; 2 transfusions, 7 fetuses; 3 transfusions, 1 fetus; 4 transfusions, 1 fetus; and 6 transfusions, 1 fetus. The mean (±SD) gestational age at the time of transfusion was 28.3 ± 4.2 weeks (range, 20.9 to 37.1 weeks). Fetal hydrops was noted at the time of transfusion on 11 occasions. Gestational age in this group of fetuses ranged from 21.0 to 37.1 weeks (mean ± SD, 27.6 ± 4.3 weeks).

Before the intrauterine transfusion, two-dimensional directed pulsed Doppler ultrasound (GE PASS II, General Electric Medical Systems, Milwaukee, Wis.) was used to obtain the time velocity integral of the aorta and main pulmonary artery at the level of the semilunar valve leaflets. A five-chamber view was used to measure the aortic time velocity integral. If the fetus was positioned with its spine posterior, the pulmonary artery was studied in a short-axis view of the great vessels, whereas if the fetal spine was anterior, a sagittal view of the ductal arch was obtained. Real-time imaging was used to adjust the Doppler angle of insonation so as to obtain measurements parallel to the axis of flow. Doppler studies were repeated within 2 hours after completion of the intravascular phase of intrauterine transfusion. All Doppler waveforms were recorded on videotape. Offline analysis was undertaken with a digitalized computer system (Digisonics, Inc., Houston, Tex.). Doppler parameters were determined from at least three consecutive waveforms and results were averaged.

Cardiac stroke volume can be calculated by multiplying the cross-sectional area of the outflow tract of a ventricle by the Doppler time velocity integral.[10] The product of the stroke volume and heart rate is the ventricular output in milliliters per minute. Cardiac output before and after intrauterine transfusion would therefore be calculated by the following equations:

$$\text{Cardiac output pretransfusion} = \text{Valve area}_1 \times \text{TVI}_1 \times \text{HR}_1$$

$$\text{Cardiac output posttransfusion} = \text{Valve area}_2 \times \text{TVI}_2 \times \text{HR}_2$$

where TVI is time velocity integral and HR is heart rate. The greatest limitation in the measurement of fetal ventricular output is related to quantitation of the diameter of valve orifices. The small size of these fetal vessels in conjunction with limitations in lateral ultrasonographic resolution can produce a large degree of error. Inasmuch as the radius of the valve orifice is squared to calculate the cross-sectional area, even the smallest error in measurement will considerably affect the outflow calculation. If we assume that the valve area remains constant, the following equations allow for detection of percent change in ventricular output:

$$\text{Because Valve area}_1 = \text{Valve area}_2$$

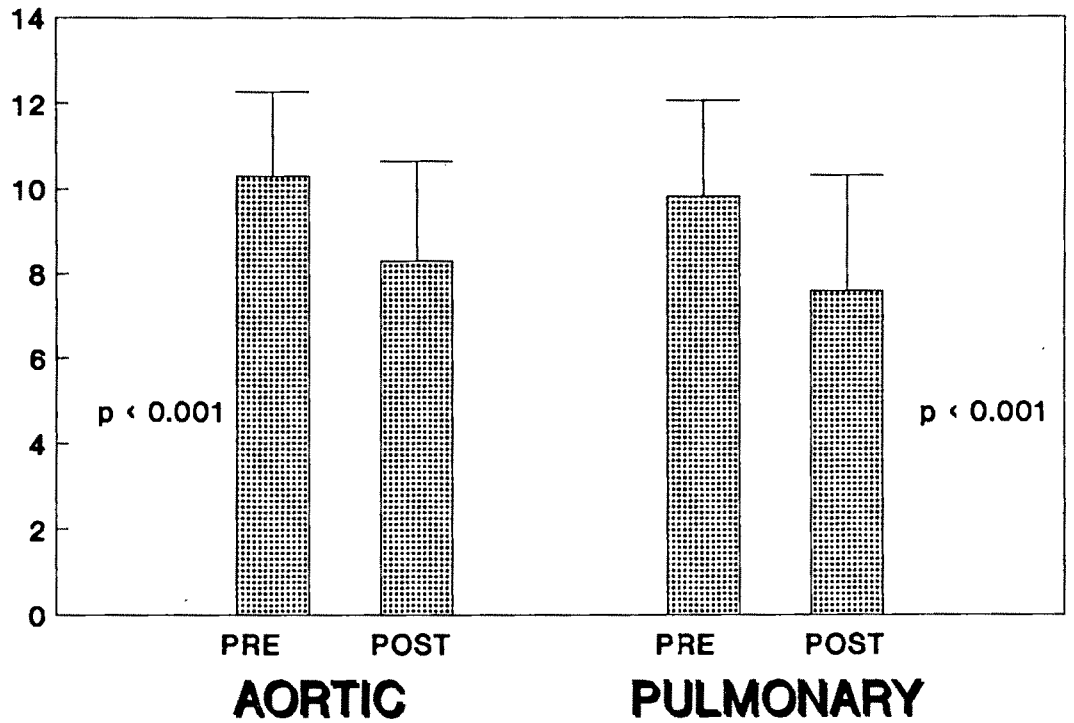

Fig. 2. Time velocity integral before and after transfusion (mean ± SD).

% Change in ventricular output =

$$\frac{(TVI_2 \times HR_2) - (TVI_1 \times HR_1)}{TVI_1 \times HR_1}$$

where TVI is time velocity integral and HR is heart rate. Colocousis et al.[11] have verified this technique in a dog model by showing that changes in left ventricular stroke volume are proportional to alterations of the aortic Doppler time velocity integral.

Noninvasive measurement of myocardial contractility has been limited to such crude parameters as M-mode measurements of changes in chamber size. With the advent of Doppler ultrasonography, waveform analysis of blood flow in the ascending aorta has been found to correlate with standard invasive techniques of left ventricular function.[12] Of the various parameters analyzed, mean acceleration (peak velocity divided by the time interval until peak velocity is achieved) was noted to be an effective measure of myocardial function.[12] Therefore we measured the mean acceleration of the Doppler waveforms from the aorta and pulmonary artery in an attempt to detect any changes in myocardial contractility after intravascular transfusion.

Intravascular transfusion was undertaken in the following manner. The cord insertion was localized with a 3 mHz sector transducer (Acuson 128, Mountain View, Calif.). Under continuous ultrasonographic guidance, a 20-gauge procedure needle was directed into the amniotic cavity. Sterile arterial pressure tubing that had been flushed with saline solution was then connected to the needle. A small amount of flush was introduced to clear the needle of amniotic fluid. Mean amniotic fluid pressure was measured continuously with a Physiocontrol VSM 1 neonatal blood pressure monitor until stable readings were obtained. The procedure needle was directed into the umbilical cord insertion and an initial sample of blood was removed for fetal hematocrit determination. Intravenous pancuronium bromide was administered to effect fetal neuromuscular blockade. A pretransfusion mean umbilical venous pressure was recorded until stable. An intravascular transfusion was undertaken with packed red blood cells until a final fetal hematocrit of 35% to 40% was attained. A final sample of fetal blood was removed, after which a posttransfusion umbilical venous pressure was obtained. As part of a combined transfusion technique,[13] a standard intraperitoneal transfusion was performed. If no amniotic fluid pressure could be obtained during the intravascular portion of the procedure as a result of an anterior placental cord insertion, amniotic fluid pressure was measured at the time of the intraperitoneal transfusion.

Mean amniotic fluid pressure was subtracted from

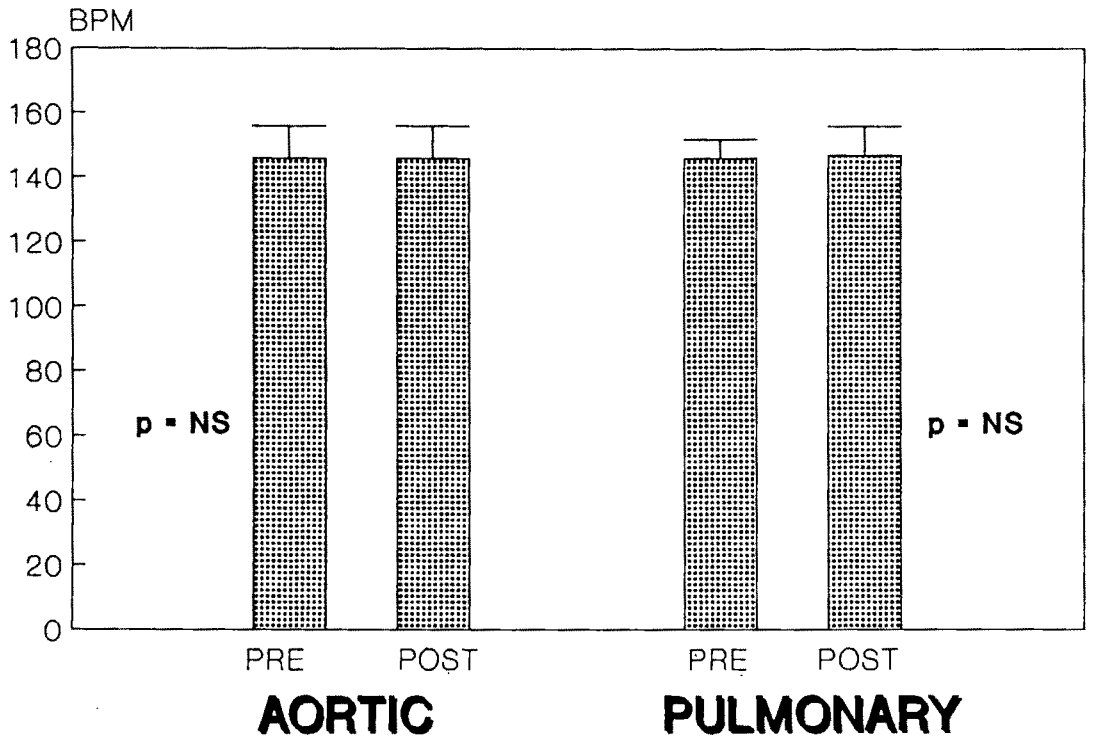

Fig. 3. Heart rate before and after transfusion (mean ± SD).

the corresponding umbilical venous pressure obtained before and after transfusion to derive the corrected umbilical venous pressure. Net volume transfused was calculated by subtracting all sample volumes removed from the volume of transfused blood. Fetoplacental volume was derived from the estimated fetal weight on the basis of ultrasonographic parameters and previously published formulas.[14, 15]

All values are reported as the mean ± SD of the mean. A normal distribution of the data was confirmed by quantile-quantile plots. Paired and unpaired two-tailed Student *t* tests were used for comparisons of data. A p value of <0.05 was considered statistically significant.

Results

The mean initial hematocrit in those fetuses without hydrops at the time of intrauterine transfusion was 27.2% ± 4.9%, whereas the final hematocrit was 36.7% ± 2.8% after a net infusion of 18.4 ± 13.9 ml of packed red cells. This volume represented an increase in the fetoplacental volume of 15.8% ± 10.9%. In those fetuses with hydrops, 35.7 ± 32.4 ml of blood were transfused (fetoplacental volume increase of 21.8% ± 12.4%) to increase the hematocrit from 19.4% ± 4.2% to 33.5% ± 5.3%.

The mean time interval between pretransfusion echocardiograms and intrauterine transfusion was 169 minutes, whereas posttransfusion echocardiograms were undertaken 79 ± 41 minutes after the intravascular phase of the procedure. Only slight fetal movement was noted during the second cardiac study. None of the fetuses exhibited episodes of bradycardia after intrauterine transfusion.

At the time of 32 of the transfusions, the amniotic fluid pressure and pretransfusion and posttransfusion umbilical venous pressures could be measured. A net increase in umbilical venous pressure of 1.7 ± 2.8 mm Hg was noted ($p < 0.01$). Fig. 1 depicts this change.

In 24 cases, Doppler analysis of the aortic outflow tract could be obtained before and after intravascular transfusion. The time velocity integral of the pulmonary valve was noted to decline significantly, whereas heart rate remained unchanged (Figs. 2 and 3). As shown in Fig. 4, a 19% mean decrease in left ventricular output (time velocity integral × heart rate) was noted. Mean acceleration in the aorta was unchanged after transfusion (Fig. 5).

In 23 cases, Doppler analysis of the pulmonary outflow tract could be obtained before and after intravascular transfusion. Pulmonary time velocity integral declined significantly after transfusion, whereas heart rate again showed no change (Figs. 2 and 3). As depicted

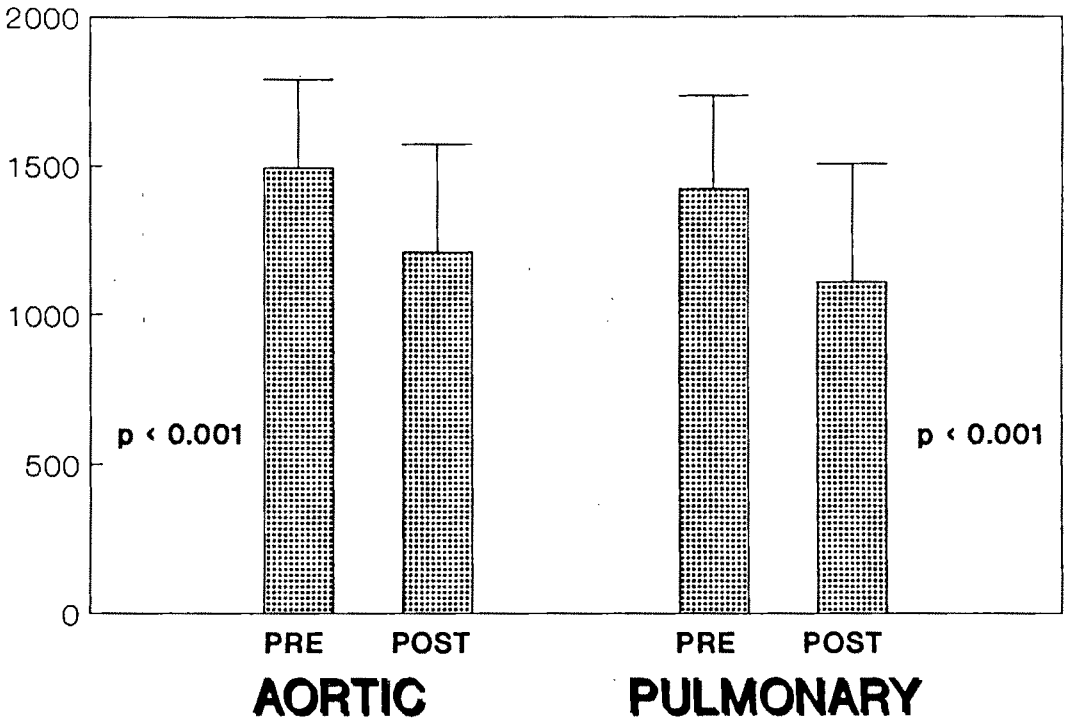

Fig. 4. Left and right ventricular output (time velocity integral × heart rate) before and after transfusion (mean ± SD).

in Fig. 4, the mean fall in right ventricular output (time velocity integral × heart rate) was 22.0%. Pulmonary mean acceleration was not significantly altered after transfusion (Fig. 5).

Because hemodynamic parameters were studied at the time of subsequent procedures in 10 of the 21 fetuses in our series, the possibility that a bias could have been introduced was entertained. For this reason, the effect of intravascular transfusion on left and right ventricular outputs was analyzed separately for the first and subsequent transfusions. At the time of eight initial transfusions, the mean decline in left ventricular output was 32.0% ($p < 0.0001$), whereas seven initial transfusions were associated with a decline in right ventricular output of 34.0% ($p < 0.001$). In 12 subsequent transfusions, left ventricular output declined 10.3% ($p = 0.02$), whereas right ventricular output fell 14.6% ($p = 0.04$). Initial transfusions were associated with a greater fall in left ventricular output than that in subsequent transfusions ($p < 0.001$). This trend was also found for right ventricular output; however, this difference did not reach statistical significance ($p = 0.06$). The differences in ventricular output at first and subsequent transfusions are depicted in Fig. 6.

To examine whether the presence of fetal hydrops affected the overall results of our study, ventricular outputs in nonhydropic fetuses were compared with measurements in hydropic fetuses. No significant difference in decline of left ventricular output was noted (mean decline, 23% versus 20%, respectively; $p = 0.23$). Right ventricular output decreased by 22% in nonhydropic fetuses and by 13% in hydropic fetuses. Again this difference was not found to be statistically significant ($p = 0.76$; Fig. 7).

Comment

In the current study, fetal cardiac output declined after acute correction of anemia by combined intrauterine transfusion. One of the limitations of our study design was that it was both cross-sectional and longitudinal in nature. To determine whether this created a bias in the results we obtained, data obtained from first and subsequent transfusions were analyzed separately. A decline in cardiac output was confirmed in both groups. It would therefore appear that our overall finding that intrauterine transfusion leads to a fall in fetal cardiac output is valid despite the use of repeated measures on some of the fetuses.

Initial transfusions were associated with a greater decline in ventricular output as compared with later transfusions. One possible explanation for this finding is that the nadir of the fetal hematocrit was more likely to be

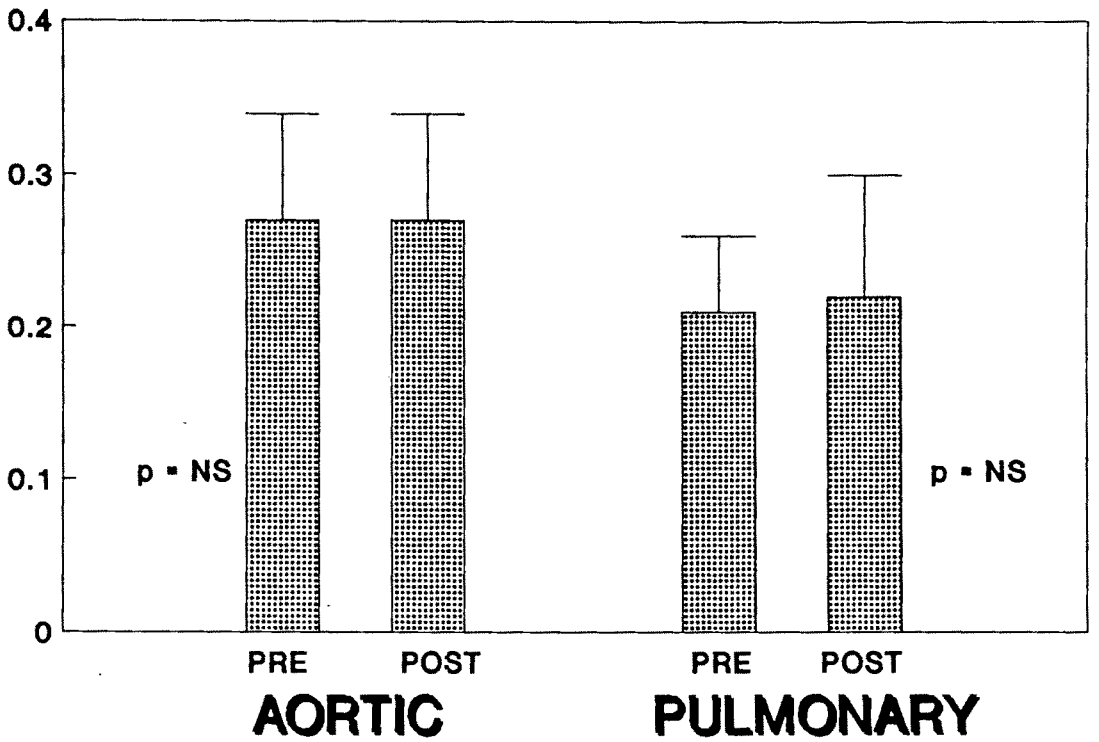

Fig. 5. Aortic and pulmonary mean acceleration before and after transfusion (mean ± SD).

present before the first transfusion before in utero therapy had been initiated. Correction of the hematocrit to a normal value would therefore involve the greatest change in hematocrit and blood viscosity during the first transfusion. Inasmuch as viscosity contributes to cardiac afterload, cardiac output would fall more during first transfusions as compared with subsequent procedures. Animal data would support this explanation. With a radioactive microsphere technique, Fan et al.[1] demonstrated in mongrel dogs that cardiac output decreased as hematocrit was increased. Murray and coworkers[16] also studied the interaction between hematocrit and cardiac output. They induced hypervolemic polycythemia in mongrel dogs with transfusions of red cells. Isovolemic exchanges with 6% dextran in saline solution were then used to lower the hematocrit. The authors confirmed an inverse relationship between cardiac output and hematocrit.

To postulate an explanation for the decline in cardiac output found in the current study, one must examine the four factors that contribute to biventricular output: heart rate, contractility, preload, and afterload. Because we used pancuronium bromide during transfusions to effect fetal neuromuscular blockade, one might argue that any cardiac effect of this drug would influence the outcome of our study. Human neonatal studies indicate that pancuronium elevates heart rate by increasing catecholamine levels.[17] Pielet et al.[18] failed to show an elevation in fetal heart rate after intrauterine transfusions in which pancuronium was used for fetal paralysis. In our series we were also unable to detect an increase in the fetal heart rate after intrauterine transfusion. The most likely explanation for these findings is that the cardioacceleratory effects of pancuronium are transitory and had abated before posttransfusion cardiac measurements were performed. In a series of 14 fetuses undergoing intravascular transfusions in which only maternal sedation was used to decrease fetal movement, Pielet and coworkers[18] noted a decline in fetal heart rate from a baseline value of 137.1 ± 3.6 to 127.9 ± 14.6 beats/min after transfusion. Although this difference did not reach statistical significance, it suggests that the fetal cardiovascular system may respond to the acute correction of anemia by a decrease in heart rate. In our study, pancuronium could have blocked such a decline in heart rate after transfusion. For this reason, the decrease in fetal cardiac output that we observed may be an underestimation of the actual fall after intrauterine transfusion. However, because an alteration in heart rate was not detected in the current study, another explanation for the decline in cardiac output must be postulated.

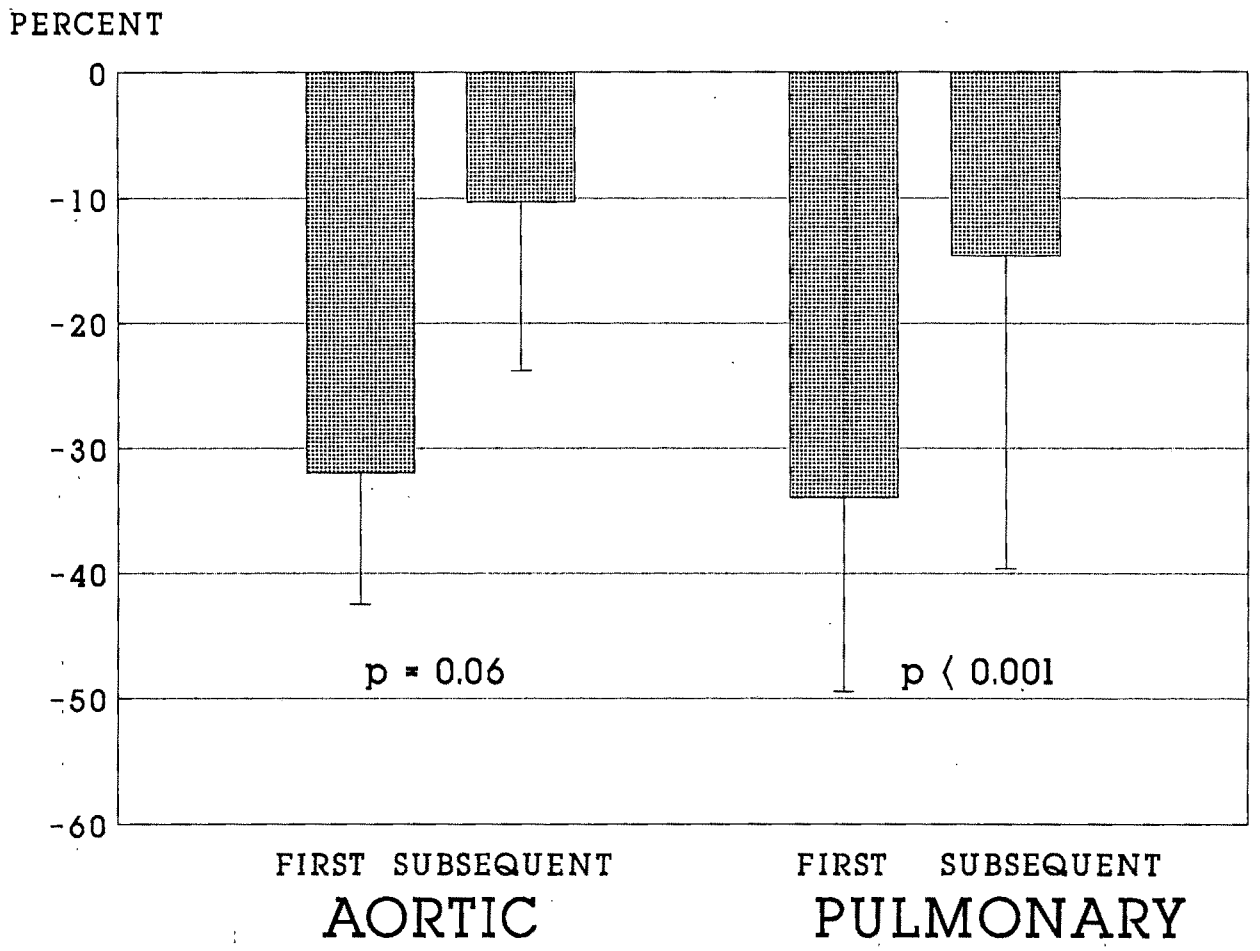

Fig. 6. Percent change in left and right ventricular output (time velocity integral × heart rate) at first transfusions as compared with subsequent procedures (mean ± SD).

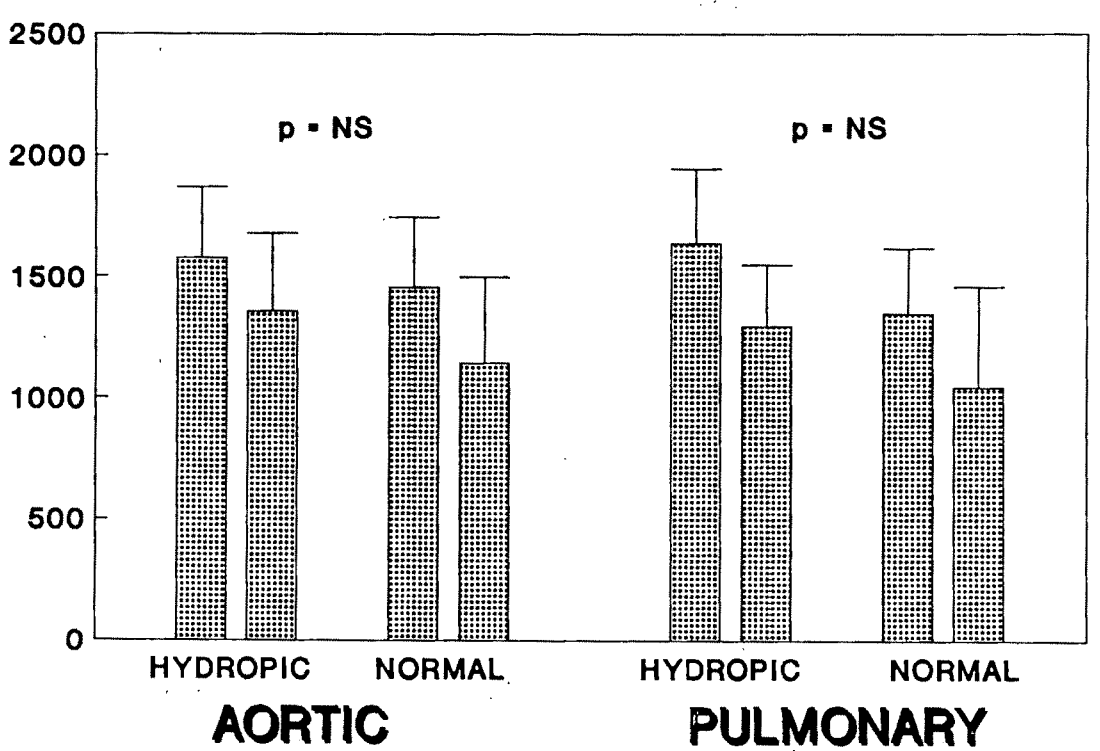

Fig. 7. Percent change in left and right ventricular output (time velocity integral × heart rate) for hydropic fetuses versus nonhydropic fetuses (mean ± SD).

If intravascular transfusion resulted in a decrease in myocardial contractility, cardiac output would be expected to decline. With mean acceleration as a measure of myocardial function, we could not detect a significant change after transfusion. This would lead us to conclude that factors other than myocardial dysfunction contributed to the observed decrease in fetal cardiac output.

In the current study, intravascular transfusion resulted in a calculated mean increase in the fetoplacental volume of 18%. In addition, umbilical venous pressure increased by a mean of 1.7 mm Hg. These findings would lead us to conclude that intravascular transfusion produced an increase in cardiac preload. Such a change in preload would be expected to effect an increase in cardiac output, or at best, produce no change at all. Available information from animal studies indicates that the fetal heart is functioning near the upper end of the Starling curve.[19] If this is true in the human fetus, one would expect no change or a small increase in ventricular output with the addition of volume to the fetal vascular space. However, we found a decline in cardiac output in our series of fetuses. We used a combined transfusion technique that consisted of the direct intravascular injection of red cells through the umbilical vein followed by a standard intraperitoneal transfusion. Nicolini and coworkers[7] reported that intraperitoneal pressure increases by a mean of 5.8 mm Hg after intraperitoneal transfusion. Therefore, although intravascular volume was increased in our fetuses, a rise in intraperitoneal pressure could have decreased venous return to the fetal heart. This might explain the fall in cardiac output noted in our study.

However, an increase in cardiac afterload would appear to offer the best explanation for the decrease in cardiac output that we noted. In two studies in the ovine fetus,[20, 21] the rapid intravascular injection of tightly packed red blood cells (hematocrit of ≥70%) produced substantial increases in mean arterial pressure. A similar rise in blood pressure in the human fetus in conjunction with the fall in cardiac output that we observed would suggest that systemic vascular resistance increased in our fetuses. In animal experiments, Fan et al.[1] noted that a progressive increase in hematocrit induced by isovolemic transfusion was associated with an increase in systemic resistance. Blood viscosity measurements revealed that this parameter may play a role in the observed increase in peripheral resistance.[1] Direct intravascular transfusion would therefore appear to result in an increase in cardiac afterload, possibly through an increase in blood viscosity. The fetal heart responds to the increased afterload by a decrease in stroke volume leading to a fall in cardiac output.

Unlike the current study, Copel et al.[6] did not find a change in cardiac output after intravascular transfusion of the human fetus. This difference may be related to the time interval before measurement of the posttransfusion cardiac output. In our study, Doppler assessment of cardiac output was undertaken within 1 hour after transfusion, whereas Copel studied his fetuses 24 hours later. These findings may indicate that hemodynamic changes occur in the human fetus during the first 24 hours after direct intravascular transfusion to allow for resolution of the decreased cardiac output that occurs immediately after the procedure. Whether this initial decrease in cardiac output is a pathologic consequence of intravascular transfusion or whether it represents a normalization of cardiac output as a result of increased oxygen delivery to peripheral tissues requires further investigation. In addition, other studies appear warranted to determine whether the decline in cardiac output is unique to the combined intravascular-intraperitoneal technique of transfusion or whether it occurs after direct transfusion alone.

Postinjection kinetics of antepartum Rh immune globulin

Frank R. Witter, MD, Rosetta S. Shirey, MS, Suzy L. Nicol, BS, and Paul M. Ness, MD
Baltimore, Maryland

The disappearance kinetics of a standard dose of 300 μg of Rh immune globulin given at 28 weeks' gestation was investigated. Ten Rh-negative unsensitized women were given 300 μg of Rh immune globulin at 28 weeks and blood samples were drawn at weekly intervals until delivery. Sera were titrated with Ror red blood cells in a saline solution–antiglobulin method. Titers ranged from 1 to 4 by the first week after injection. In nine of 10 patients the titers were zero at 49 to 70 days after injection. With R_2R_2 red blood cells and LISS, papain, polybrene, or a combination of methods, Rh immune globulin could still be detected until delivery in four of the nine patients. Because these serologic methods can detect 5 ng/ml anti-D, five of 10 subjects may not have been protected for 8 to 29 days before delivery. This study indicates that a titer of ≤4 is expected for passively acquired anti-D during pregnancy, and that antepartum administration of Rh immune globulin may not always produce detectable passive antibody for as long as theoretically predicted. (AM J OBSTET GYNECOL 1990;163:784-6.)

Key words: Rh sensitization, Rh disease, erythroblastosis fetalis, Rh hemolytic disease

The administration of 300 μg of Rh immune globulin at 28 to 29 weeks' gestation to unsensitized Rh-negative mothers is the common practice in the United States. This practice is based on pioneering studies by Boman et al.[1] In the first study, 300 μg of Rh immune globulin was administered at 28 and 34 weeks to 1204 women who ultimately were delivered of Rh-positive infants. No woman became sensitized, although historically 21 would have been expected to have been sensitized with only postpartum prophylaxis. On the basis of a theoretical calculation based on the half-life of gamma globulin, it was expected that a single injection of 300 μg of Rh immune globulin at 28 weeks would provide protection for 12 weeks or 84 days. Therefore antepartum prophylaxis with a single injection at 28 weeks was implemented. After implementation of this program the incidence of Rh isoimmunization decreased from 3.5 per 1000 births at risk with only postpartum prophylaxis to 2.0 per 1000 births at risk with both antepartum and postpartum prophylaxis.[2]

With consideration of the half-life of γ-globulin, a 300 μg dose of Rh immune globulin theoretically should result in a residual dose of 20 μg at 12 weeks after injection.[1] The level of residual Rh immune globulin is important because doses in the 10 to 20 μg range have been shown to actually enhance immunization of Rh-negative volunteers to similar small doses of Rh-positive cells.[3] However, enhancement has never been demonstrated in clinical practice.

This study was undertaken to determine if under clinical conditions, intramuscular administration of 300 μg of Rh immune globulin at 28 weeks' gestation does

produce detectable passive antibody for 12 weeks or 84 days. In addition, we sought to determine the maximal titers of Rh immune globulin observed after injection.

Material and methods

After approval of this study by the Institutional Human Investigation Committee, we enrolled 10 informed, consenting, Rh-negative unsensitized pregnant women in this study. All women had Rh-positive male partners and were therefore at risk of carrying a Rh-positive fetus.

According to standard clinical practice, each woman received 300 μg of Rh immune globulin at 28 to 29 weeks' gestation by intramuscular injection in the deltoid muscle. Before injection all women were documented by antibody screening tests to be unsensitized to the Rh antigen. After injection titers were drawn at weekly intervals until delivery. The serum samples were stored frozen at −40° C until all samples from each subject were collected. Samples from each subject were then titrated in parallel by a standard saline solution–antiglobulin method.[4] The indicator red blood cells were from a D-heterozygous donor with Rh genotype Ror.

Samples that failed to react in titration studies were further tested for the presence of passive anti-D by use of more sensitive techniques that included the use of R_2R_2 indicator red cells and LISS, papain, or polybrene methods or a combination.[6]

The Rh immune globulin used for this study was provided by Rorer Pharmaceutical Corporation (Ft. Washington, Pa.). A single lot was used for subjects 1 through 9 and a second lot was used for subject 10. All Rh immune globulin was stored before use as specified by the package insert to maintain potency.

Results

All 10 subjects were documented to have no endogenous anti-D before Rh immune globulin administration. After injection all subjects demonstrated anti-D at titers of 1 to 4 within the first week. Titers between 1 and 2 persisted in all subjects through 42 days after injection. Subject four was delivered at 56 days after injection with a positive titer of 1. The other subjects' titers decreased to zero before delivery at 49 to 70 days after administration of Rh immune globulin (Table I).

Samples from the nine subjects who had no demonstrable anti-D before delivery in titration studies were further tested with more sensitive techniques. Four subjects had demonstrable antenatal Rh immune globulin until delivery, whereas in five subjects no anti-D could be demonstrated as early as 55 days after injection. Table II lists the days after injection until the first undetectable sample or delivery for the nine subjects with Rh titers of zero before delivery. Thus, half the subjects in this study were without detectable Rh immune globulin levels for 8 to 29 days before delivery (Table III).

Comment

The absence of detectable anti-D by our more sensitive serologic methods in 50% of our subjects for 8 to 29 days before delivery is not consistent with the presence of 20 μg of Rh immune globulin at 84 days after injection as predicted by the theoretical half-life of gamma globulin. Our more sensitive serologic methods can detect <0.005 μg/ml of anti-D. If 20 μg of anti-D were present, given the mean plasma volume of our subjects of 3400 ml, the anti-D concentration in the sera should have been 0.006 μg/ml and therefore would have been detectable by our methods.

Commercially available Rh immune globulin was used in this study. Food and Drug Administration standards require at least 300 μg to be present; however, a 300 μg dose may contain slightly more than 300 μg. This possible variation in the amount of Rh immune globulin might account for some variability in the

disappearance of antepartum Rh immune globulin. Its effect should have been to lengthen the time to disappearance from that theoretically predicted for 300 μg.

No subject in the study had antepartum bleeding. We had no clinical reason to suspect that fetal-maternal bleeding could account for the disappearance of the anti-D antibody, and two of the subjects without detectable Rh immune globulin had Rh-negative fetuses. We therefore believe that these are valid findings representing variations in the biologic half-life of Rh immune globulin. This variation in the biologic half-life of Rh immune globulin is not unique to the anti-D preparation that we studied. In applying our sensitive serologic assays to samples taken at delivery from patients known to have been injected with Rh immune globulin from two other manufacturers at less than 84 days before delivery, we found from 40% to 90% of the patients were without detectable anti-D levels.

The rate of sensitization with postpartum Rh immune globulin alone has been shown to be 3.5/1000 births at risk.[2] With the addition of a single antepartum injection of Rh immune globulin at 28 weeks the rate of sensitization can be lowered to 2.0/1000 births at risk.[2] In the original antepartum prophylaxis study by Boman et al.[1] in which 300 μg of Rh immune globulin was administered at 28 and 34 weeks, no sensitizations were found. Because of the rarity of antepartum sensitization the difference in sensitization rates between one and two doses of antepartum Rh immune globulin may be a result of sampling error. However, it would appear from our data that administration of 300 μg of antepartum Rh immune globulin may not always produce detectable passive antibody for 84 days and that rare sensitizations may be a result of early disappearance of antepartum Rh immune globulin.

Finally, a dose of 300 μg of Rh immune globulin should not be expected to produce a titer >4. Therefore in clinical practice the upper limit for passively acquired anti-D titers should be 4.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Magnesium sulfate and promethazine do not interact to cause hypotension in gravid ewes

Kenneth L. Pollack, MD, David H. Chestnut, MD, Carl P. Weiner, MD, Christine S. Thompson, and Craig S. DeBruyn

Iowa City, Iowa

The purpose of this study was to determine whether magnesium sulfate and promethazine interact to cause hypotension in gravid ewes. Fifteen experiments were performed in five chronicaly instrumented animals between 125 and 130 days of timed gestation (term = 145 days). In one group of experiments each animal received magnesium sulfate (4 gm intravenous bolus followed by 4 gm/hr intravenous infusion) then promethazine (50 mg intravenously). In a second group each animal received magnesium sulfate then saline solution as a control. In a third group each animal received saline solution then promethazine. Infusion of magnesium sulfate increased the mean (±SEM) serum magnesium concentration to 5.7 ± 0.6 and 6.6 ± 0.6 mg/dl in the magnesium sulfate–promethazine and magnesium sulfate—saline solution groups, respectively. Magnesium sulfate slightly decreased maternal mean arterial pressure ($p < 0.05$) and increased cardiac output ($p < 0.05$) in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups. Otherwise there were no significant changes in maternal mean arterial pressure or cardiac output in any group. Promethazine increased maternal heart rate ($p = 0.0001$) in both the magnesium sulfate–promethazine and saline solution–promethazine groups. Magnesium sulfate increased uterine blood flow ($p < 0.01$) in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups, but promethazine blunted the increase in uterine blood flow associated with magnesium sulfate. Similarly, magnesium sulfate decreased uterine vascular resistance ($p < 0.01$) in both the magnesium sulfate–promethazine and magnesium sulfate-saline solution groups, but promethazine eliminated the decrease in uterine vascular resistance associated with magnesium sulfate. Maternal and fetal arterial blood gas and acid-base values did not change in any group, except that there was a small, near-significant decrease ($p = 0.06$) in fetal pH 10 minutes after promethazine was given in the magnesium sulfate–promethazine group. We conclude that magnesium sulfate and promethazine did not interact to cause maternal hypotension in normovolemic gravid ewes. However, promethazine increased maternal heart rate and blunted the increase in uterine blood flow associated with magnesium sulfate. (Am J Obstet Gynecol 1990;163:787-94.)

Key words: Magnesium sulfate; phenothiazines, promethazine; pregnancy

Promethazine is a phenothiazine that possesses antiemetic, antihistaminic, and sedative properties. Magnesium sulfate is frequently used for seizure prophylaxis in preeclampsia and for tocolysis in preterm labor. A common side effect of magnesium sulfate is nausea. Some obstetricians give promethazine to treat the nausea associated with magnesium sulfate therapy. Bourgeois et al.[1] observed profound hypotension in two women with preeclampsia who received both magnesium sulfate and promethazine 25 mg intravenously. Frohlich[2] subsequently suggested that an interaction between magnesium sulfate and promethazine may have been responsible for the hypotension. He asserted that promethazine, through its inhibition of phosphodiesterase and calmodulin, might cause hypotension when it is administered with magnesium sulfate. (Inhibition of phosphodiesterase can cause vasodilation via an increase in β-adrenergic activity.[3, 4] Calmodulin inhibition can cause hypotension by direct relaxation of vascular smooth muscle.[5]) Magnesium sulfate also inhibits calmodulin and is a direct calcium antagonist.[6] Therefore magnesium sulfate and promethazine might have a synergistic effect on vascular smooth muscle tone and thereby cause profound hypotension. The purpose of this study was to determine whether magnesium sulfate and promethazine interact to cause maternal hypotension in gravid ewes.

Material and methods

The protocol was approved by the University of Iowa Animal Care Committee. Mixed breed ewes were obtained at approximately 118 days of timed gestation

(term = 145 days). Each animal fasted for 36 hours before operation. At 120 days' gestation induction of general anesthesia was accomplished with thiopental sodium (8 to 12 mg/kg). After tracheal intubation anesthesia was maintained with 40% nitrous oxide, 60% oxygen, and 1% to 1.5% halothane. Mechanical ventilation was maintained throughout operation. With sterile technique laparotomy and hysterotomy were performed, and catheters (polyethylene 90) were inserted into the fetal descending aorta via each femoral artery and into the amniotic cavity. After the hysterotomy and laparotomy incisions were closed, a left paramedian incision was made. The left uterine artery was isolated via a retroperitoneal approach, and an electromagnetic flow probe (Dienco, Los Angeles) was placed around the artery. Catheters (polyethylene 240) were then inserted into the maternal descending aorta and inferior vena cava via the left mammary artery and vein, respectively. All catheters were tunneled subcutaneously and exteriorized through a small incision in the left flank. Finally, an Fr. 8.5 introducer (AK09800, Arrow, Reading, Pa.) was inserted percutaneously into the right jugular vein.

After operation each animal was kept in an approved cage in a restricted area, fed a balanced diet, and allowed a recovery period of at least 5 days. Procaine penicillin G 500,000 U and dihydrostreptomycin 625 mg (Combiotic, Pfizer, New York) were given to the mother intramuscularly before operation and daily for 3 days after operation. Gentamicin 80 mg was given to the mother intravenously the day of each experiment, and gentamicin 40 mg was given via amniotic catheter during operation and the day of each experiment.

Each experiment was performed with the animal standing unrestrained within an approved transport cart. Before the first experiment in each animal, a pulmonary artery catheter (No. 93A-131H-7F, American Edwards Laboratories, Santa Ana, Calif.) was inserted through the jugular vein introducer. At the end of each experiment the catheter was withdrawn into the superior vena cava, and sterility was maintained with an 80 cm sheath.

The experimental sequence was as follows:

1. Hydration with 250 ml normal saline solution intravenously over 15 minutes.
2. One hour was allowed for baseline measurements.
3. At time zero a 50 ml intravenous bolus was given over 5 minutes (either 4 gm magnesium sulfate in saline solution or saline solution alone).
4. At 5 minutes an intravenous infusion of magnesium sulfate (4 mg/hr) in saline solution or saline solution alone was given. The total volume of crystalloid infused was 100 ml/hr in each group.
5. At 120 minutes a 20 ml intravenous bolus was given over 2 minutes (either promethazine 50 mg in saline solution or saline solution alone).

The infusion of magnesium sulfate (or saline solution alone) was continued through 180 minutes. Hemodynamic measurements were continued through 210 minutes.

Fifteen experiments were performed in five chronically instrumented gravid ewes. There were three experimental groups. In one group (magnesium sulfate–promethazine) each animal received magnesium sulfate then promethazine. In a second group (magnesium sulfate–saline solution) each animal received magnesium sulfate then saline solution. In a third group (saline solution–promethazine) each animal received saline solution then promethazine. All three experiments were performed on each animal, in random order. Only one experiment was performed per day, and each animal rested at least 24 hours between experiments.

Maternal arterial blood pressure, central venous pressure, pulmonary artery pressure, and fetal arterial blood pressure were measured continuously via disposable strain gauge pressure transducers (No. 46951-02, Abbott Critical Care Systems, North Chicago). Fetal pressures were corrected by subtraction of simultaneous intraamniotic pressure. Mean arterial blood pressure was computed arithmetically. The maternal heart rate and fetal heart rate were computed from the arterial waveforms. Uterine artery blood flow was measured continuously with a quantitative electromagnetic flowmeter (No. RF-2500, Dienco, Los Angeles) in three of five animals (i.e., nine of 15 experiments). Arterial and venous pressures, heart rates, and uterine artery blood flow were recorded at 10-second intervals with a customized data acquisition system (Coulbourn Instruments, Lehigh Valley, Pa.) interfaced with a personal computer (PCXT, IBM, Rochester, Minn.).

Maternal cardiac output was determined at baseline and at 10, 120, 130, 180, and 210 minutes. Measurements were made in triplicate with 10 ml of iced saline solution and a thermodilution cardiac output computer (No. 9520, American Edwards Laboratories).

Maternal and fetal arterial blood gas and pH values were determined at baseline and at 120, 130, 180, and 210 minutes with an Instrumentation Laboratory (No. 1302, Leighton, Mass.) blood gas analyzer. All values were corrected for temperature. Maternal serum magnesium concentrations were determined at baseline and at 10, 120, 130, 180, and 210 minutes by a bichromatic colorimetric assay.

Statistical analysis was by three-factor analysis of variance, followed by t tests for individual measurements.

Bonferroni correction was applied as appropriate. A value of $p < 0.05$ was considered significant.

Results

The mean (±SEM) weight of the animals was 66 ± 4 kg. Baseline maternal and fetal hemodynamic, blood gas, and acid-base measurements were similar in the three groups (Tables I and II). Magnesium sulfate administration caused similar increases in maternal serum magnesium concentrations in the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups. At 120 minutes mean (±SEM) serum magnesium concentrations were 5.7 ± 0.6 mg/dl in the magnesium sulfate–promethazine group and 6.6 ± 0.6 mg/dl in the magnesium sulfate–saline solution group. (These concentrations were within the therapeutic range for seizure prophylaxis[7, 8] and tocolysis[9, 10] in pregnant women.) Serum magnesium concentrations did not change in the saline solution–promethazine group.

At 10 minutes magnesium sulfate slightly decreased maternal mean arterial pressure ($p < 0.05$) in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups (Fig. 1). At no other time did maternal mean arterial pressure significantly differ from baseline in any group. Specifically, there was no significant change in maternal mean arterial pressure after promethazine administration in either the magnesium sulfate–promethazine group or the saline solution—promethazine group.

Magnesium sulfate did not significantly alter maternal heart rate (Fig. 2). Promethazine increased maternal heart rate ($p = 0.0001$) in both the magnesium sulfate–promethazine and saline solution–promethazine groups. Maternal heart rate remained stable within the magnesium sulfate–saline solution group.

Maternal central venous pressure and pulmonary capillary wedge pressure did not change significantly in any group. At 10 minutes magnesium sulfate slightly increased maternal cardiac output ($p < 0.05$) in both magnesium sulfate–promethazine and magnesium sulfate–saline solution groups (Fig. 3). At no other time did maternal cardiac output significantly differ from baseline in any group.

At 120 minutes magnesium sulfate had increased uterine blood flow to 120% ± 5% of baseline ($p = 0.005$) in the magnesium sulfate–promethazine group and to 122% ± 4% of baseline ($p = 0.002$) in the magnesium sulfate–saline solution group (Fig. 4). Uterine blood flow remained significantly greater than baseline until the completion of the experiment in the magnesium sulfate–saline solution group. In contrast, promethazine blunted the increase in uterine blood flow in the magnesium sulfate–promethazine group. Uterine blood flow did not change singificantly in the saline solution–promethazine group.

Magnesium sulfate decreased uterine vascular resistance ($p < 0.01$) at 10 and 120 minutes in both the magnesium sulfate–promethazine and the magnesium sulfate–saline solution groups (Fig. 5). Uterine vascular resistance remained significantly below baseline

Table I. Baseline maternal hemodynamic, acid-base, and blood gas measurements

	Magnesium sulfate–promethazine	*Magnesium sulfate–saline solution*	*Saline solution–promethazine*
Mean arterial pressure (mm Hg)	92 ± 3	93 ± 2	95 ± 3
Central venous pressure (mm Hg)	3 ± 2	3 ± 2	4 ± 1
Pulmonary wedge pressure (mm Hg)	7 ± 1	8 ± 2	8 ± 2
Heart rate (beats/min)	102 ± 7	109 ± 3	109 ± 3
Cardiac output (L/min)	8.2 ± 0.9	8.3 ± 1.3	9.6 ± 1.2
Uterine blood flow (ml/min)	553 ± 200	464 ± 108	500 ± 140
Intraamniotic pressure (mm Hg)	8 ± 3	6 ± 3	8 ± 1
Arterial pH	7.41 ± 0.02	7.42 ± 0.02	7.43 ± 0.02
Arterial P_{O_2} (mm Hg)	104 ± 3	105 ± 3	102 ± 5
Arterial P_{CO_2} (mm Hg)	37 ± 1	37 ± 1	37 ± 0.4
Serum magnesium (mg/dl)	1.4 ± 0.1	1.2 ± 0.1	1.4 ± 0.1

All values are expressed as mean ± SEM.

Table II. Baseline fetal hemodynamic, acid-base, and blood gas measurements

	Magnesium sulfate–promethazine	*Magnesium sulfate–saline solution*	*Saline solution–promethazine*
Mean arterial pressure (mm Hg)	43 ± 3	45 ± 3	46 ± 4
Heart rate (beats/min)	169 ± 7	165 ± 11	152 ± 14
Arterial pH	7.34 ± 0.004	7.34 ± 0.01	7.35 ± 0.01
Arterial P_{O_2} (mm Hg)	20 ± 1	20 ± 1	21 ± 1
Arterial P_{CO_2} (mm Hg)	48 ± 2	48 ± 1	48 ± 2

All values are expressed as mean ± SEM.

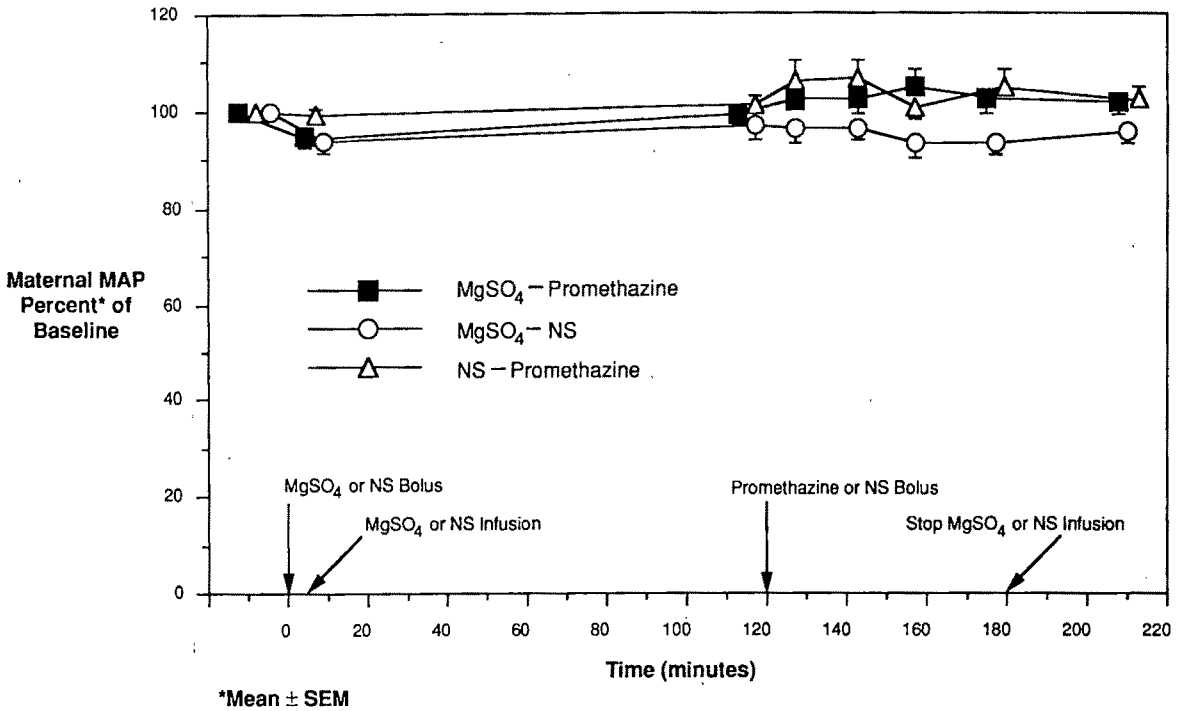

Fig. 1. Maternal mean arterial pressure *(AMP)* responses over time. All values are expressed as mean ± SEM. Magnesium sulfate decreased maternal mean arterial pressure ($p < 0.05$) at 10 minutes in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups.

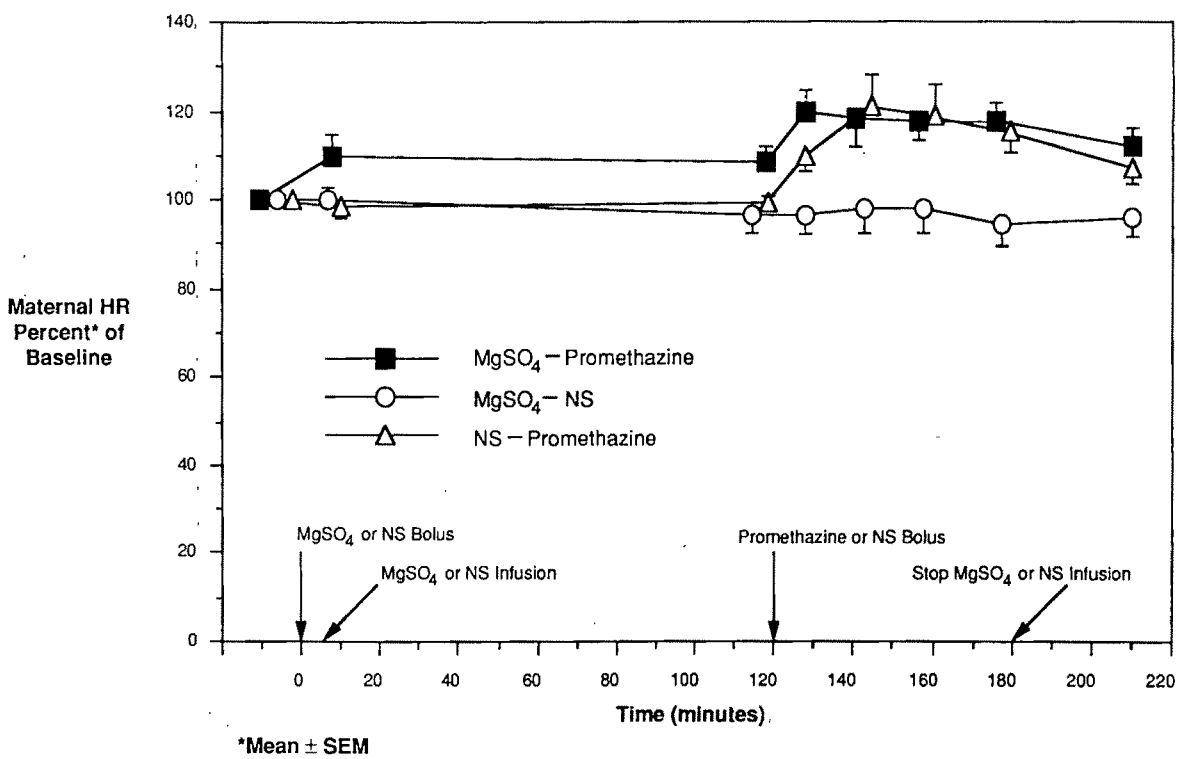

Fig. 2. Maternal heart rate *(HR)* responses over time. All values are expressed as mean ± SEM. There was a significant increase in maternal heart rate ($p < 0.01$) at each measurement between 130 and 210 minutes in the magnesium sulfate–promethazine group and between 130 and 180 minutes in the saline solution–promethazine group.

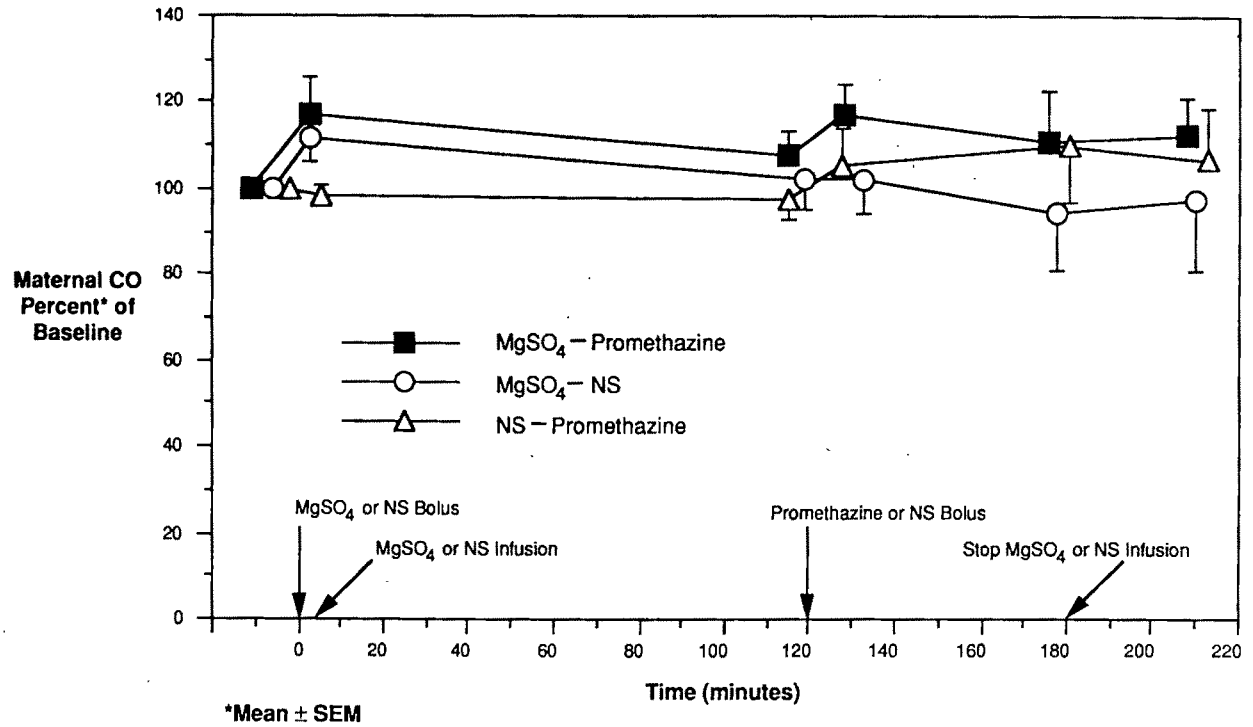

Fig. 3. Maternal cardiac output *(CO)* responses over time. All values are expressed as mean ± SEM. There was a significant increase in maternal cardiac output ($p < 0.05$) at 10 minutes in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups.

until the completion of the experiment in the magnesium sulfate–saline solution group. In contrast, in the magnesium sulfate–promethazine group promethazine eliminated the decrease in uterine vascular resistance associated with magnesium sulfate. (Promethazine did not significantly alter systemic or pulmonary vascular resistance in either the magnesium sulfate–promethazine or saline solution–promethazine group.)

Magnesium sulfate decreased intraamniotic pressure ($p < 0.01$) in both the magnesium sulfate–promethazine and magnesium sulfate–saline solution groups. The addition of promethazine did not significantly alter intraamniotic pressure in either the magnesium sulfate–promethazine or saline solution–promethazine group. Thus the increase in uterine vascular resistance after promethazine did not result form an increase in uterine tone.

Maternal arterial pH, P_{O_2}, and P_{CO_2} did not change significantly in any group. Similarly, fetal heart rate, mean arterial pressure, and arterial P_{O_2} and P_{CO_2} did not change significantly in any group. However, there was a near-significant decrease ($p = 0.06$) in fetal pH at 130 minutes (i.e., 10 minutes after promethazine administration) in the magnesium sulfate–promethazine group (Fig. 6). The decrease in pH was small and resolved within 1 hour.

Comment

Several investigators have studied the hemodynamic effects of magnesium sulfate in gravid ewes. Dandavino et al.[11] and Ayromlooi et al.[12] observed small, transient decreases in maternal mean arterial pressure and increases in uterine blood flow shortly after administration of an intravenous bolus of magnesium sulfate. Similarly, in the present study magnesium sulfate decreased maternal mean arterial pressure 5% to 6% and increased uterine blood flow 20% to 22%. In addition, magnesium sulfate caused a transient increase in maternal cardiac output, which is consistent with earlier unpublished observations in gravid ewes.

In the present study the dose of magnesium sulfate (4 gm bolus and 4 gm/hr infusion) was similar to that used in other studies of gravid ewes.[11-13] Also, this dose of magnesium sulfate resulted in serum magnesium concentrations within the therapeutic range for seizure prophylaxis[7,8] and tocolysis[9,10] in pregnant women. We elected to give a 50 mg dose of promethazine. This is twice the dose that was administered to the patients reported by Bourgeois et al.[1] but within the range (i.e., 25 to 75 mg) used clinically.

Magnesium sulfate and promethazine did not interact to cause hypotension in the present study, but this does not prove that a drug interaction was not respon-

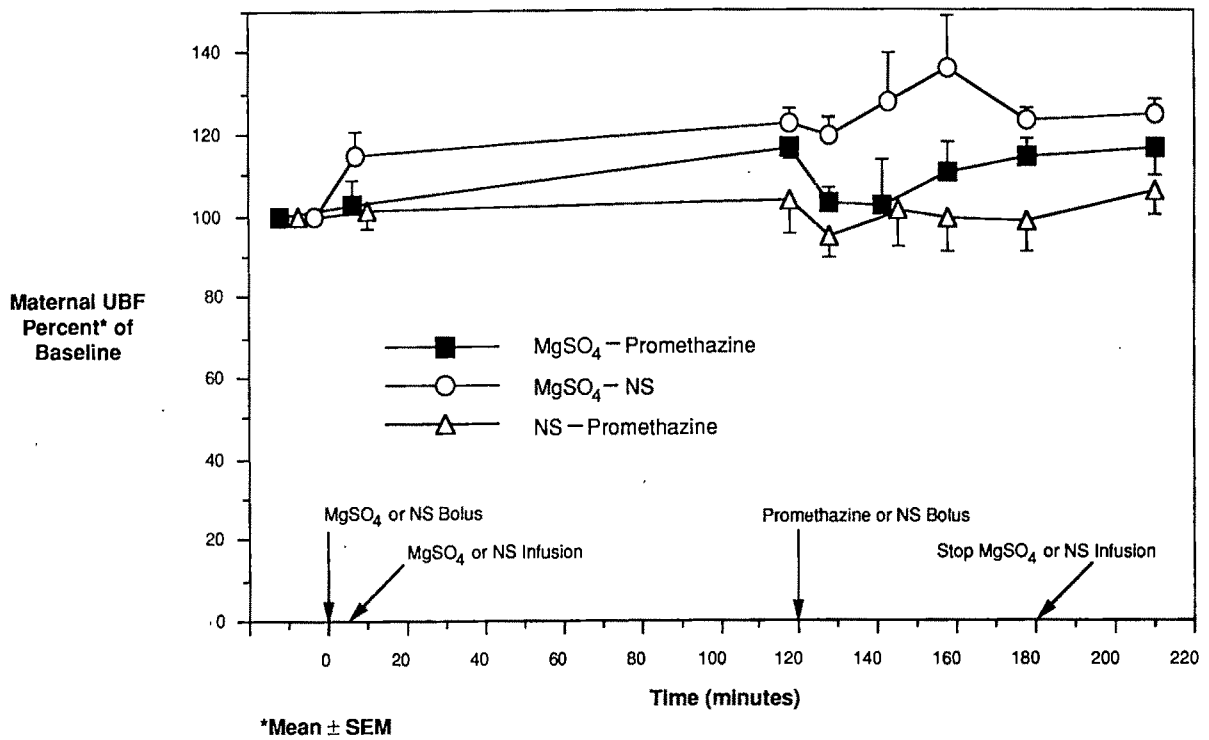

Fig. 4. Maternal uterine artery blood flow *(UBF)* responses over time. All values are expressed as mean ± SEM. There was a significant increase in maternal uterine blood flow at 10 and 120 minutes in the magnesium sulfate–promethazine group ($p = 0.005$) and at each measurement between 10 and 210 minutes in the magnesium sulfate–saline solution group ($p < 0.01$).

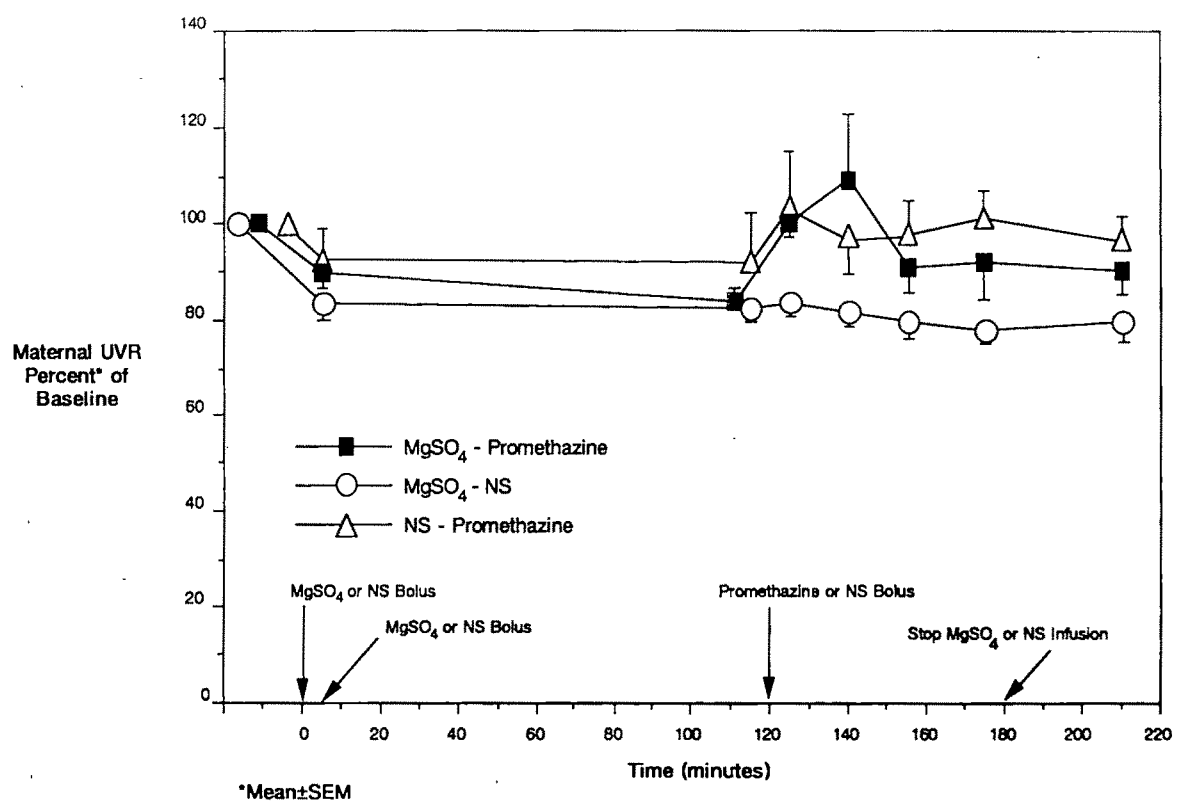

Fig. 5. Maternal uterine vascular resistance *(UVR)* responses over time. All values are expressed as mean ± SEM. There was a significant decrease in maternal uterine vascular resistance at 10 and 120 minutes in the magnesium sulfate–promethazine group ($p < 0.01$) and at each measurement between 10 and 210 minutes in the magnesium sulfate–saline solution group ($p < 0.01$).

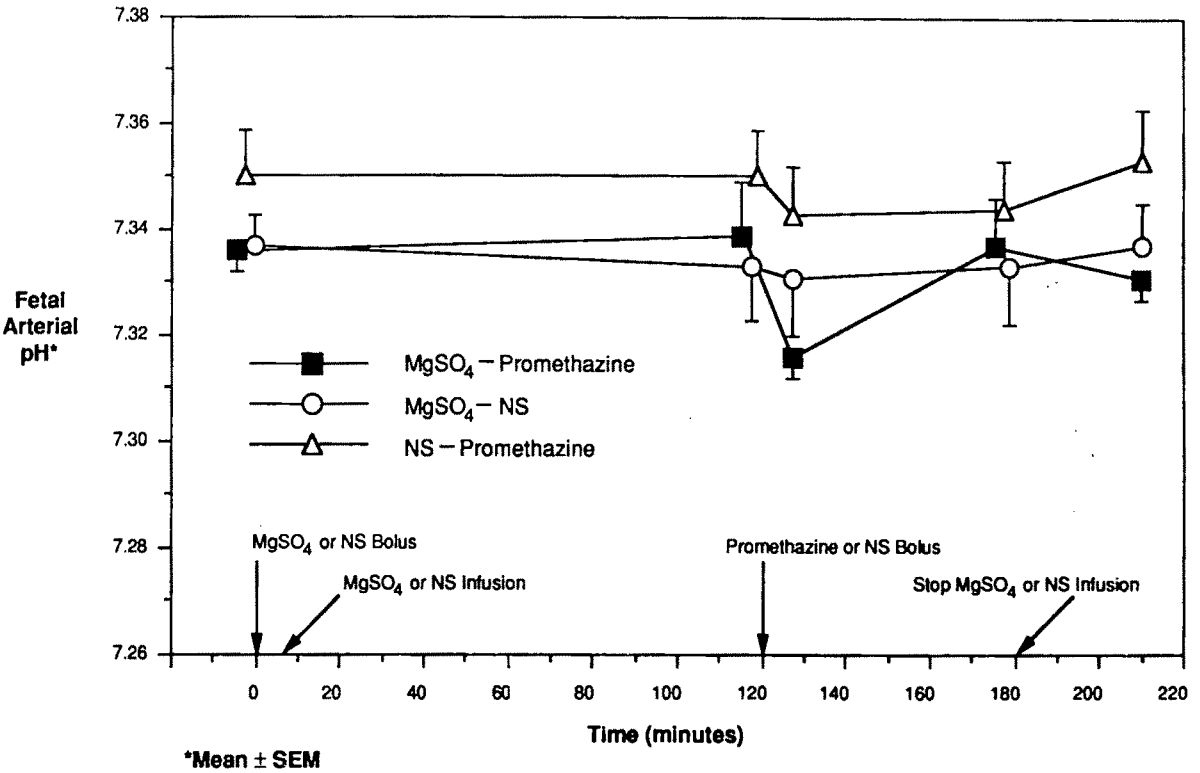

Fig. 6. Fetal arterial pH responses over time. All values are expressed as mean ± SEM. Fetal arterial pH decreased at 130 minutes in the magnesium sulfate–promethazine group ($p = 0.06$).

sible for the profound hypotension reported by Bourgeois et al.[1] First, we acknowledge the difference in species. Second, their two patients had preeclampsia and hypovolemia. In contrast, our animals were normovolemic before each experiment. (In the present study each animal received 250 ml of saline solution intravenously 1 hour before the start of each experiment). Third, magnesium sulfate and promethazine might have an adverse interaction in only a small percentage of animals or patients. Bourgeois et al.[1] stated that their patients frequently receive both magnesium sulfate and promethazine, yet profound hypotension was noted in only two patients.

While some believe that promethazine may exacerbate hypotension in the presence of hypovolemia, there is evidence to the contrary. Goetsch et al.[13] showed that administration of promethazine before hemorrhage improves both hemodynamic stability and survival in dogs. They speculated that the antihistaminic action of promethazine reduced vasodilation and thus raised blood pressure during hypovolemia.

It is interesting that promethazine increased uterine vascular resistance but had no significant effect on systemic and pulmonary vascular resistance, mean arterial pressure, or cardiac output. One possible explanation for this effect is that the anticholinergic effects of promethazine decreased the opposition to sympathetic tone. Elevated sympathetic tone is associated with increased uterine vascular resistance and decreased uterine blood flow in gravid ewes.[14, 15] Similarly, promethazine's anticholinergic properties may have resulted in the increased maternal heart rate observed in the present study.

We conclude that magnesium sulfate and promethazine did not interact to cause maternal hypotension in normovolemic gravid ewes. However, promethazine increased maternal heart rate and blunted the increase in uterine blood flow associated with magnesium sulfate. This interaction was associated with a small, transient decrease in fetal arterial pH. One must be cautious before extrapolating data from pregnant sheep to pregnant women. Further, one should not extrapolate these data to patients with preeclampsia and intravascular volume depletion. Nonetheless, this study suggests the need for further study of interactions between magnesium sulfate and phenothiazine drugs in pregnancy.

Uterine hyperstimulation after low-dose prostaglandin E_2 therapy: Tocolytic treatment in 181 cases

Christian H. Egarter, MD,[a] Peter W. Husslein, MD,[a] and William F. Rayburn, MD[b]

Vienna, Austria, and Omaha, Nebraska

There is limited information about uterine hyperstimulation after low-dose prostaglandin E_2 therapy. The purpose of this retrospective study was to describe our combined experience with this undesired effect by use of three techniques for prostaglandin E_2 administration. Uterine hyperstimulation was present if the contraction frequency was more than five in 10 minutes or if contractions exceeded 2 minutes in duration. A total of 181 cases were evaluated during a 51-month period. The rates of hyperstimulation were 7.3% (167/2297) in the group that received intravaginal tablets (3.0 mg), 2.9% (12/408) with intravaginal gel (2.5 mg), and 0.5% (2/394) with intracervical gel (0.5 mg). Hyperstimulation usually began within the first hour for the group that used gel and within the first 4 hours for the tablet group. A β_2-adrenergic drug (hexoprenaline or terbutaline) was infused routinely without adverse effects and with rapid resolution of the worrisome findings in 178 (98.3%) cases. The remaining three cases required cesarean delivery and had no evidence of neonatal compromise. We conclude from this large, combined series that uterine hyperstimulation after low-dose prostaglandin E_2 therapy is uncommon and usually rapidly reversible with β_2-adrenergic therapy without apparent untoward effects. (AM J OBSTET GYNECOL 1990;163:794-6.)

Key words: Uterine hyperstimulation, prostaglandin E_2, cervical ripening

Many double-blind investigations have demonstrated the value of prostaglandin E_2 (PGE_2) for cervical ripening or induction of labor.[1] Although the primary aim of (PGE_2) therapy is often cervical ripening, uterine contractions occur coincidentally but are usually "silent" or mild. A major concern is the possibility of excess uterine activity leading to impaired uteroplacental perfusion.

The world literature contains only limited information about PGE_2-induced uterine hyperstimulation; such reports include either individual cases with relatively high doses or a small number of cases in comparative drug trials.[2-5] The purpose of this study was to report the combined experience at our two maternity centers. We reviewed the frequency of hyperstimulation associated with three methods of drug delivery

(intravaginal tablet, intravaginal gel, intracervical gel) and described therapeutic results of β_2-adrenergic tocolytic therapy.

Material and methods

Cases at term (38 to 43 weeks) that required PGE_2 therapy before induction of labor were studied between January 1985 and March 1989. The pregnancies were not complicated by fever, vaginal bleeding, ruptured amniotic membranes, major fetal malformation, or known sensitivity to prostaglandins. The principal medical indications for cervical ripening included postdate pregnancies, hypertension, diabetes, and suspected fetal growth retardation.

Protocols before and after dosing were similar at the two maternity centers. Bishop scoring had been performed and a cervical score assigned in each case.[1] Prerequisites for PGE_2 therapy included a reassuring fetal heart rate (FHR) tracing (preferably a reactive nonstress test), informed patient consent, and absence of regular uterine contractions. Before treatment the upper vagina and cervix were swabbed free of any discharge or excess mucus.

Commercially available PGE_2 preparations in Vienna included a 3 mg vaginal tablet (Prostin E_2 vaginal tablet, Upjohn Ltd, Crawley, Sussex) and a 0.5 mg triacetin-based gel (Prepidil, Upjohn Ltd, Crawley, Sussex). According to protocol the gel was applied intracervically in cases of a cervical Bishop score of 0 to 3, whereas a tablet was inserted intravaginally when the Bishop score was between 4 and 6.[6] In Omaha a 2.5 mg cellulose-based gel was compounded in the hospital pharmacy and instilled intravaginally in cases of a cervical Bishop score of 0 to 4.[1]

All patients remained recumbent for at least 1 hour after PGE_2 administration with continuous electronic monitoring of the FHR and uterine activity. Monitoring was continued if regular uterine contractions developed. After a minimum 6-hour period the PGE_2 therapy was repeated if there was no labor or significant change in Bishop score ($\geq$3 points). Otherwise labor was induced with oxytocin beginning at 6 to 12 hours after dosing.

Uterine hyperstimulation was defined as a contraction frequency of more than five in 10 minutes or contractions exceeding a 2-minute duration.[7] For treatment of uterine hyperstimulation the patient was placed on her left side, given oxygen, and a β_2-adrenergic drug was administered. In Vienna hexoprenaline (Gynipral, Chemic Linz, Ling, Austria) was used intravenously starting at a rate of 0.3 μg/min, whereas in Omaha terbutaline (Brethine, Geigy, Ardsley, N.Y.) was administered as a single 250 μg dose intravenously or subcutaneously. Treatment was considered successful if contractions became less frequent with either reversal of any FHR decelerations or relief of any maternal discomfort. Continuous electronic monitoring occurred during active labor (cervical dilation $\geq$3 cm), and an amniotomy was performed as early as safely possible.

Results

Of a total of 3099 cases of low-dose PGE_2 therapy, 181 (5.8%) had evidence of uterine hyperstimulation during the 51-month period. Nulliparity was more common with stimulation (105/181, 58.0% vs 1188/2913, 40.7%; χ^2 21.7, p 0.001). Hyperstimulation occurred with similar frequency when the Bishop score was 4 to 6 compared with 0 to 3 (167/2860, 5.8% vs 14/239, 5.9%).

Hyperstimulation was observed in 7.3% (167/2297) of the group that received intravaginal tablets, 2.9% (12/408) of the intravaginal gel group, and 0.5% (2/394) of the intracervical gel group. This condition began after dosing within the first hour (24 ± 27 minutes, mean ± SD; range, 1 to 73 minutes) or within the first 4 hours in all intravaginal tablet cases.

Episodes of FHR abnormalities occurred in 31.5% (57/181) study cases. These patterns consisted of variable decelerations or bradycardiac episodes 1 to 5 minutes in duration. This finding was most common when contractions began and usually lasted throughout a recordable contraction.

Administration of a β_2-adrenergic drug was successful in normalizing uterine contractions and reversing any FHR abnormality in 178 (98.3%) cases. This normalization usually began within 5 minutes (range, 1 to 13 minutes) after tocolytic therapy regardless of the hyperstimulation pattern. Contractions persisted in three cases (one intravaginal gel, two intravaginal tablets) despite multiple doses of hexoprenaline or terbutaline. Although cesarean delivery was necessary in cases of persistent FHR decelerations, each infant did well with a 5-minute Apgar score $\geq$8 and umbilical artery pH value >7.20. The β_2-adrenergic therapy was not associated with any long-standing maternal cardiovascular side effects.

No intrapartum complications were attributable to PGE_2-induced uterine hyperstimulation. Any FHR abnormalities or uterine hypertonicity (failure of the uterus to relax between contractions or contractions in which the basal tone remained elevated for at least 2 minutes) appeared several hours after PGE_2 therapy. Cesarean delivery was necessary in 17 (9.4%) of the hyperstimulation cases for failure to progress (nine cases), fetal distress (six cases), and failed induction (two cases). Catastrophic side effects, such as a uterine rupture or amniotic fluid embolism, were not found.

Comment

PGE_2, a potent oxytocic agent, is helpful in changing cervical consistency and initiating labor. Nearly all patients would be expected to have mild uterine activity after the application of a low-dose of PGE_2 applied intracervically or intravaginally. Uterine contractions may be desirable if the goal is to ripen the cervix by myometrial contractions in addition to affecting cervical connective tissues.[4] Of much concern are excessive uterine contractions that became so frequent or sustained to warrant tocolytic therapy.

This descriptive study reports the experience with uterine hyperstimulation at two regional perinatal centers. Despite a heterogenous patient population, observations were combined to expand knowledge about this adverse effect with different PGE_2 preparations (0.5 mg intracervical gel, 2.5 mg intravaginal gel, 3.0 mg vaginal tablet). All three methods for drug delivery and dosing have been described previously, and our written protocols for predosing and postdosing monitoring were similar.

The incidence of uterine hyperstimulation in this investigation varied from 0.5% to 7.3%. A more favorable cervix (predose Bishop score of 4 to 6) or multiparity was not found to be contributory. Uterine hyperstimulation usually appeared within minutes after either intracervical or intravaginal gel application, because absorption velocities are rapid.[6] With tablets as a vehicle the lag time was prolonged up to 4 hours. The increased rate of hyperstimulation in the intravaginal tablet subgroups may be explained by the higher dose, different method of delivery, or closer proximity of the drug to the more fully exposed endocervical tissues. We consider our experience with use of intravaginal tablets to be clinically useful as more experience is being gained with use of PGE_2-containing intravaginal suppositories and pessaries.[6-8]

Observations from this noncomparative study also confirm the ease in reversing hyperstimulation with β_2-adrenergic therapy. Results from this large number of cases support previous impressions from isolated case reports or small series of patients. A description of other therapeutic measures is beyond the scope of this report but would include swabbing or irrigating the vagina or administering magnesium sulfate intravenously. Although these techniques may be helpful, administration of β-sympathomimetics has been described most commonly. Our limited experience with attempts at removing the gel has not been encouraging, and the use of intravenous magnesium sulfate is more time consuming and perhaps less rapid in normalizing uterine contractions.

We did not find intrapartum FHR patterns and uterine contractions to be influenced by any prior hyperstimulation. We have previously demonstrated by intrauterine pressure recordings that mothers given the 3 mg PGE_2 vaginal tablet had intrapartum uterine activities that were not statistically or clinically different from those of a control group with spontaneous labor.[9] Evidence for uterine hypertonicity during active labor was uncommon despite earlier hyperstimulation from PGE_2 therapy.

When low-dose PGE_2 is administered for cervical ripening or labor induction, close monitoring remains essential. This practice would permit tocolytic therapy to be instituted early to reverse any excessive PGE_2-induced contractions. Observations from this collective series revealed that uterine hyperstimulation after PGE_2 therapy is uncommon and can be rapidly reversed without apparent untoward intrapartum effects. β_2-Adrenergic therapy may be safely used to normalize excess uterine activity.

Prevalence of use of cocaine and other substances in an obstetric population

Cristina Matera, MD, Wendy B. Warren, MD, Maureen Moomjy, MD, Daniel J. Fink, MD, and Harold E. Fox, MD
New York, New York

Increasing use of cocaine among pregnant women has been reported. This study was conducted to determine the prevalence of positive urine toxicologic screens for cocaine and other substances of patients admitted to the Sloane Hospital for Women. Urine samples were obtained from 509 women admitted to the delivery suite. The overall prevalence of cocaine was 10% (n = 51). Cocaine use was 10 times more prevalent in the clinic population (14%) than in the private population, (1.4%). In addition, women whose urine samples were positive for cocaine were more likely to have no prenatal care, previous induced abortions, to be human immunodeficiency virus–positive, and admitted previous use of cigarettes, alcohol, cocaine, and other drugs. Amphetamines were detected in 13% (n = 65) of patients. However, the screens did not distinguish between metabolites of amphetamines and other drugs such as cold medications. The medical history alone predicted only 37% (n = 19) of the cocaine-positive screens and none of the amphetamine-positive screens. (Am J Obstet Gynecol 1990;163:797-801.)

Key words: Cocaine, amphetamines, pregnancy, urine toxicologic screening

An escalation of cocaine use in the United States throughout the 1970s and 1980s has been well documented.[1] Significant adverse perinatal and neonatal effects of cocaine use in pregnancy have been reported including low birth weight, prematurity, abruptio placentae, and impaired neonatal behavioral assessment scores.[2-7] Studies in pregnant ewes have demonstrated significantly elevated maternal arterial pressure and decreased uterine blood flow during cocaine infusion, suggesting the pathophysiologic mechanisms that may cause these neonatal effects.[8, 9]

At the Sloane Hospital for Women in New York City the devastating effects of cocaine use are frequently observed in the obstetric and neonatal services. In a previous retrospective study we reviewed the results of all urine toxicologic screens sent from our labor room in 1987 and 1988. Cocaine was the drug most commonly identified. However, because of the selection of patients screened no conclusions regarding the prevalence of cocaine use could be made (data presented at Ninth Annual Meeting of Society of Perinatal Obstetricians, New Orleans, Louisiana, February 2-4, 1989, Abstract 79).

Several studies have examined the prevalence of cocaine use in pregnant women.[10-12] These investigations, all conducted in large teaching hospitals, have identified prevalence rates from 8% to 17% in pregnant women. Because the pattern of drug abuse varies according to location and patient population, we surveyed urine toxicologic screens in the parturients to determine the prevalence of cocaine and other substance abuse.

Methods

This investigation was conducted from mid-November to Dec. 31, 1988, at the Sloane Hospital for Women. The study population included all women with pregnancies >20 weeks' gestation admitted consecutively to the labor suite for labor, premature rupture of membranes, or delivery by oxytocin induction or cesarean section. Routine urine samples were obtained for protein analysis. A portion was labeled with an anonymous numeric code, was frozen at −20° C and was stored for 2 to 4 months.

Demographic information, past medical and obstetric history, prenatal course, complications, and a record of all medications administered in the labor suite were obtained from the patient's medical record and labeled with the same numeric code. No informed consent was obtained because all data were recorded anonymously. This study was approved by the Institutional Review Board of the hospital.

The urine specimens were subsequently thawed and screened by enzyme immunoassay using EMIT reagents (Syva Corporation, Palo Alto, Calif.).[13] Urine was tested for the following drugs, their metabolities, or

both: cocaine, opiates, methadone, amphetamines, barbiturates, benzodiazepines, ethanol, and phencyclidine.

Urine samples were not available from all study patients because some were delivered too quickly or the specimen was inadvertently discarded. To determine the effect of this incomplete sampling, the same demographic and historical data were obtained on patients for whom no urine toxicologic screen was collected.

The data were analyzed with χ^2 analysis and t test when appropriate. Tests were considered statistically significant for values of $p < 0.05$. The Bonferroni correction was made when applicable.

Results

We obtained urine specimens and historical data for 509 women during the study period. At the same time we collected historical data but no urine specimen for 105 women. These two populations are compared in Table I. The patients for whom no urine was obtained (the nonscreened group) were more likely to be multiparous ($p < 0.01$) and to have had a previous preterm delivery ($p < 0.05$). There was also a higher percentage of white women and a lower percentage of Hispanic women in this group ($p < 0.05$). The nonscreened group contained a higher percentage of private patients compared with the study population, although this difference was not statistically significant. There were no differences in age, history of cigarette, alcohol, or cocaine use, or lack of prenatal care between these two groups.

Among the study patients 159 urine toxicologic screens were positive for drugs or their metabolites. In 36 patients this could have resulted from medications administered during the labor room stay; for example, opiates (meperidine) given during labor. These 36 patients were excluded from subsequent analysis. Thus 123 (24%) of all urine specimens studied were considered positive.

The distribution of drugs detected in the urine screens is shown in Table II. Cocaine or its metabolites and amphetamines were found in 10% ($n = 51$) and 13% ($n = 65$) of the population, respectively. Cocaine was found more commonly in the clinic population (14%, $n = 49$) than the private population (1.4%, $n = 2$). The detection of amphetamines in the two groups was similar: 14% ($n = 49$) in clinic patients and 11% ($n = 16$) in the private patients. All 13 patients found to have metabolites of marijuana in their urine were on the clinic service.

Cocaine was most likely to be detected alone ($n = 30$); when found with other drugs, cocaine was most often combined with marijuana ($n = 7$) or amphetamines ($n = 6$). Other substances infrequently ($n < 3$) detected with cocaine included opiates, barbiturates, methadone, and alcohol.

The demographic and historical information of women who had negative urine toxicology screens and those with positive tests for cocaine or amphetamines is shown in Table III. When the women with positive screening results for amphetamines were compared with the women whose results were negative for all substances, there was no statistically significant differ-

ence in age, service, ethnic group, parity, or use of other substances. However, women with positive tests for cocaine were less likely to be on the private service and more likely to have had no prenatal care than those with negative results for any drug ($p < 0.05$). There was no difference in parity or previous preterm deliveries in the two groups. However, 52% ($n = 27$) of women with positive tests for cocaine had previous induced pregnancy terminations compared with 29% ($n = 101$) in the negative group ($p < 0.01$). In addition, women in the cocaine-positive group were more likely to give a history of cigarette, alcohol, cocaine, or other drug use. There was a higher percentage of black women and a lower percentage of white women in the cocaine-positive group; however, these differences were not statistically significant. When the women with positive results for both cocaine and amphetamines were excluded from the analysis, the statistical significance of the comparisons was not altered.

Overall complications were higher among the women with positive cocaine tests (Table IV). Anemia was more common among the cocaine group compared with the patients with negative results ($p < 0.05$). This tendency was not seen in the amphetamine-positive group. Abruptio placentae was seen in 4% ($n = 2$) of women with positive tests for cocaine and in 1.4% ($n = 5$) among those with negative tests. These numbers are too small for statistical analysis. Three patients with known human immunodeficiency virus–positive results were delivered during the study period and all had screens positive for cocaine.

In the cocaine-positive group, more women were admitted for labor or rupture of membranes at less than 37 weeks' gestation compared with women who had

negative urine toxicology screens ($p < 0.05$). Several women who had positive test results for amphetamines received β-sympathomimetic medications for treatment of premature labor. Because metabolites of these drugs would be identified by the EMIT reagents as amphetamines, these patients were among those excluded from the analysis of the positive toxicology group. Therefore our data on premature labor in the amphetamine-positive patients cannot be interpreted.

In the entire screened population, 24 women gave a history of cocaine use alone or in combination with other drugs. The urine screens for four of these women were negative for any drugs. Cocaine alone or in combination with other drugs was detected in 19 patients; amphetamines were found in one. Three patients reported past use of drugs other than cocaine. Two of these had positive results for cocaine and one had a negative screen.

Comment

Cocaine use during pregnancy has reached epidemic proportions in inner-city populations.[10-12] Our data show that the prevalence of cocaine use in our clinic population is similar to that reported in other studies. Private patients had positive test results for cocaine use with less frequency.

Although we did not have toxicology screens performed for our entire population, the demographic analysis revealed no consistent differences between the screened and nonscreened groups. The higher parity among the latter suggests that they were delivered before a urine specimen could be obtained. Although there was a difference in ethnic distribution between the screened and nonscreened women, the two groups were similar with respect to all factors that were associated with cocaine use.

A surprising finding was the high prevalence of amphetamine use. Patients who had positive test results for amphetamines were clearly demographically different from those who used cocaine. As a class of drugs, amphetamines are sympathomimetic agents that produce stimulation of α- and β-adrenergic receptors. This results in elevated blood pressure and pulse. The user describes a sense of well-being, decreased fatigue, and enhanced sensory perception. Amphetamines are considered to have a high abuse potential.[14] Although effects of amphetamine use in pregnancy have not been widely investigated, the reported maternal and neonatal consequences of amphetamine use do not appear to be as dramatic as those of cocaine.[15-18]

β-Sympathomimetics, decongestants, and common over-the-counter anorexiants can yield positive toxicologic results for amphetamines. The historic data collection did not include recent use of the above medications, except for ephedrine use in association with regional anesthesia and β-sympathomimetics for tocolysis. The use of decongestants and anorexiants in a laboring woman is often not suspected, inquired about, or documented in the medical records. Further studies are needed to confirm our findings.

The EMIT reagents detect cocaine use within 24 to 72 hours of obtaining the specimen. Other studies have shown that a careful history is needed to elicit prior drug use.[19] The historical data from the patients' records were obtained by residents, nurses, and attending physicians working in a busy labor suite. It is likely that a thorough history of drug use was not taken. Therefore the actual rate of drug use in our population may be higher than reported in this study. Other methods of drug detection such as hair analysis may allow a more complete identification of substance use during pregnancy.[19]

In conclusion, we found a high prevalence of cocaine and amphetamines in urine toxicology screens in

women admitted to our labor suite. Drug use was rarely detected by routine medical history alone. The high prevalence of amphetamine use has not been reported by others and merits further study. Our data demonstrate that urine toxicology screening of all pregnant women is necessary if all women and infants at risk for the complications of drug abuse are to be identified and treated.

We thank the labor and delivery nurses for their assistance in collecting the urine samples. We also thank Curtis Davis, MT, and Ivy Fonseca, BS, for their assistance in processing the urine toxicologic screens.

A comparison of the effect of epidural, general, and no anesthesia on funic acid-base values by stage of labor and type of delivery

Jaye M. Shyken, MD, James S. Smeltzer, MD, L. V. Baxi, MD, Karin J. Blakemore, MD, Steven E. Ambrose, MD, and Roy H. Petrie, MD, ScD

St. Louis, Missouri

The effect of epidural anesthesia on neonatal acid-base status, before, during, and after labor, was determined by review of funic blood-gas values from 142 women with normal term pregnancies and normal fetal heart rate patterns. Funic acid-base parameters were compared by type of anesthesia when stratified by mode of delivery (vaginal, cesarean section in the active phase of labor, or elective cesarean section). Use of epidural analgesia for vaginal delivery was associated with significantly longer labor, lower umbilical arterial pH, higher arterial P_{CO_2} and arterial bicarbonate values. In women who had cesarean section in the active phase of labor, use of epidural anesthesia was associated with significantly lower arterial and venous P_{O_2} values when compared with women who received general anesthesia. Patients who had elective cesarean section with epidural anesthesia had funic acid-base values similar to women who had general anesthesia. Epidural analgesia-anesthesia offers no clear advantage to the uncompromised term fetus. (AM J OBSTET GYNECOL 1990;163:802-7.)

Key words: Acid-base balance, umbilical cord, obstetric anesthesia

It is commonly believed that use of epidural anesthesia offers an advantage to the fetus over general anesthesia. Gale et al.[1] studied a group of women who had cesarean sections and found a greater incidence of acidemia, hypercarbia, and need for respiratory assistance in infants born under general anesthesia. Other investigators found that use of general anesthesia results in lower Apgar scores and increased need for neonatal resuscitation when compared with use of a regional anesthetic.[2, 3] Some authors document no difference in neonatal condition with respect to funic acid-base values, 1- and 5-minute Apgar scores, and time to sustained respiration between infants born by elective cesarean section under epidural anesthesia versus general anesthesia.[4]

Conversely, use of epidural anesthesia, despite its known safety, is associated with a reduction in maternal blood pressure,[5] which is the primary determinant of uterine blood flow. Medications given to combat hypotension may also impair uterine perfusion.[6]

The definition of normal values for acid-base parameters depends largely on the population under study.[7, 8] Umbilical arterial acid-base parameters reflect the impact of intrapartum events and specifically aid in the evaluation of the depressed newborn.[9, 10]

The effect of mode of anesthesia on immediate neonatal outcome as measured by umbilical cord acid-base balance has not been completely elucidated for both vaginally delivered and abdominally delivered patients. The purpose of this investigation was to determine the impact of type of anesthesia, by type of delivery, on a carefully selected group of uncompromised infants born to normal women after an uncomplicated term pregnancy. We analyzed funic acid-base status with or without epidural analgesia in the absence, midst, and conclusion of labor, that is, at elective cesarean section, at cesarean section performed in the active phase of labor, and at vaginal delivery, respectively.

Patients and procedures

Barnes Hospital patient charts from January 1986 through December 1987 were reviewed. The study population consisted of 142 women who were delivered of infants weighing 2500 to 3999 gm, at 36 to 41⅐ weeks' gestation, with normal fetal heart rate patterns and available umbilical arterial and venous acid-base values. No patients with induced labors were included. Patients with antenatal risk factors thought to impact on acid-base status were also excluded from study. All medical and obstetric complications of pregnancy that could potentially contribute to adverse neonatal out-

6/6/22340

come were excluded (e.g., diabetes mellitus, hypertensive illnesses, antepartum hemorrhage, asthma, sickle cell disease, Rh isoimmunization, and congenital malformations). Criteria for exclusion on the basis of fetal heart rate patterns were as follows: late decelerations, severe variable decelerations (to 60 beats/min for 60 seconds), prolonged decreased short-term or long-term variability, baseline tachycardia of ≥160 beats/min, and prolonged bradycardia (>5 minutes) within 30 minutes of delivery. Those pregnancies complicated by thick meconium (>2+ on a scale from 0 to 4+) were also excluded.

These patients were stratified into six groups based on mode of anesthesia and type of delivery. Group 1 contained women with spontaneous vaginal deliveries without regional anesthesia. They may have received narcotic analgesia or local anesthesia for labor and delivery. Group 2 subjects had spontaneous vaginal deliveries with epidural analgesia. Group 3 patients had cesarean section during the active phase of labor with general anesthesia. Group 4 was composed of women who underwent cesarean section during the active phase of labor with epidural anesthesia. Subjects were excluded from groups 3 and 4 for cervical dilatation <4 cm and cesarean section before the onset of active labor, as defined by Friedman.[11] Groups 3 and 4 were nonelective, surgical deliveries primarily in women after an arrest of labor or because of malpresentation in active labor. The use of oxytocin constituted an exclusion criterion for all but groups 3 and 4, in whom it was used as needed for augmentation of labor. Women in group 5 had cesarean delivery before the active phase of labor with general anesthesia. Group 6 patients underwent cesarean section without active labor with epidural anesthesia. Groups 5 and 6 were largely composed of patients having elective or semielective cesarean sections.

Funic blood was collected from a doubly clamped segment of umbilical cord immediately after vaginal or cesarean delivery. The samples were iced and within 15 minutes of collection, pH, P_{O_2}, P_{CO_2}, and hemoglobin levels were directly measured with a Radiometer (Copenhagen) blood gas analyzer model ABL 2. Base excess (deficit) was calculated.

Anesthesia was conducted by an anesthesiologist or nurse anesthetist as follows. Those undergoing general anesthesia for cesarean section, while positioned in left lateral tilt position, had a rapid-sequence induction and were preoxygenated with 100% oxygen in all cases. Thiopental sodium, 3 to 5 mg/kg, and succinylcholine, 1.0 to 1.5 mg/kg, were used before intubation with cricoid cartilage pressure. Those undergoing epidural analgesia for labor received volume loading with 500 to 1000 ml of lactated Ringer's solution before placement of a catheter in the epidural space. A test dose of 2% lidocaine with epinephrine was given, followed by an analgesic dose of 0.125% to 0.25% bupivacaine hydrochloride with or without fentanyl, 50 to 100 μg, at the discretion of the anesthesiologist. Perineal anesthesia was accomplished with 1.5% lidocaine or 2% to 3% 2-chloroprocaine. Epidural anesthesia for cesarean section was performed under similar conditions; however, 0.5% bupivacaine hydrochloride or 3% 2-chloroprocaine was used at a dose appropriate for the patient's height to achieve a block at the level of T4-6. For cesarean section volume preload was 1500 to 2000 ml of normal saline solution. Intravenous ephedrine, in 5 mg increments, was used in all cases of hypotension refractory to hydration and change in maternal position.

Table I. Description of groups

Group	*Description*	*n*
1	Vaginal delivery without anesthesia	29
2	Vaginal delivery with epidural analgesia	25
3	Cesarean section in active labor with general anesthesia	16
4	Cesarean section in active labor with epidural anesthesia	24
5	Elective cesarean section with general anesthesia	21
6	Elective cesarean section with epidural anesthesia	27

The unpaired Student *t* test was used to compare means from the groups associated with epidural analgesia, anesthesia, or both, and those without. Nonparametric data were compared with Fisher's exact test. Duration of labor was logarithmically transformed to a normal distribution. Multiple analysis of variance, general linear models analysis of variance and covariance, and stepwise multiple regression were used for multiple comparisons.

Results

One hundred forty-two women were included in the study. The patients were divided into the six defined groups by mode of anesthetic and type of delivery (Table I). Demographic characteristics of the study population are presented in Table II. Demographic characteristics were similar among groups; however, the patients in group 2 were younger and of lower parity than those in group 1 ($p < 0.05$ and $p < 0.005$, respectively). Length of gestation and birthweight were similar among groups compared.

Table III demonstrates the indications for cesarean section by group. The category of "other" in group 3 included an infant with an asymptomatic funic presentation noted on ultrasonographic scan. Group 5 women included one patient who had a scheduled cesarean

Table II. Demographic data

hysterectomy, one with idiopathic thrombocytopenic purpura, one with a scheduled cholecystectomy, and two with maternal intracranial arteriovenous malformations. The decision with regard to the form of anesthesia was largely determined by indication for cesarean section and by the presence or absence of an indwelling epidural catheter. Acidosis, defined as umbilical arterial pH ≤ 7.15,[12] was not observed in any group.

Funic arterial and venous acid-base results are presented in Table IV. Fig. 1 graphically demonstrates the arterial pH data for the six groups. There were statistically significant differences in arterial pH, P_{CO_2}, and bicarbonate between groups 1 and 2. There also were significantly lower values of arterial and venous P_{O_2} in the newborns from the group 4 compared with group 3. No significant differences between funic acid-based values were evident between groups 5 and 6.

There were no infants with Apgar scores <7 at 5 minutes in any of the groups studied. There were seven infants with Apgar scores <7 at 1 minute: one (3.4%) in group 1, one (4.0%) in group 2, two (8.3%) in group 4, and three (14.3%) in group 5. These differences were not statistically significant, even for group 5 versus group 6 ($p = 0.077$, Fisher's exact test).

Hypotension necessitating administration of ephedrine occurred in each of the three epidural analgesia/anesthesia groups. Ephedrine was required in 5 of 25 patients (20%) in group 2, 7 of 24 cases (29%) in group 4, and 14 of 27 (52%) in group 6. This finding is not surprising when the increased dosage of epidural agent required to achieve surgical anesthesia over labor analgesia is considered. The occurrence of hypotension did not affect the overall results of the eight outcome measures (Wilkes' lambda [10, 66.5] = 0.8917, $p = 0.540$) or any of the individual outcome measures ($p > 0.2$).

Women treated with epidural analgesia had longer labors. The patients in group 1 had a mean stage I duration of 7.78 ± 5.23 hours and mean stage II duration of 0.33 ± 0.29 hours. The mean length of labor in group 2 was 13.09 ± 7.94 hours, and 0.87 ± 0.50 hours for stages I and II, respectively. Among vaginally delivered infants the highly significant difference in active-phase labor duration between epidural compared with no anesthesia ($F = 9.64$, $p < 0.01$) was not explained by parity ($F = 0.00$, $p = 1.00$). There was an increased duration of the second stage with nulliparity ($F = 12.98$, $p < 0.001$) and with use of epidural anesthesia ($F = 16.53$, $p < 0.001$), which were independent of each other ($F = 1.45$, $p = 0.23$).

For the women who were delivered vaginally in groups 1 and 2, multiple statistical analyses were made of significant acid-base differences to control for parity, duration of active labor, duration of second stage, and to determine a source of the observed differences. Funic arterial pH was significantly higher in parous than in nonparous patients. The effect of anesthesia on pH was significant even when controlled for parity ($p < 0.05$). There was a fall in pH observed with increased duration of the second stage of labor ($p < 0.05$). The effects on pH of nulliparity and epidural anesthesia were dependent on longer duration of the second stage of labor. Active-phase duration of labor demonstrated no effect on pH. Similarly, the decrease in funic venous P_{O_2} in the epidural group was dependent on length of second-stage labor. The observed increased arterial P_{CO_2} and bicarbonate levels in group 2 were not dependent on duration of labor, duration of the second stage of labor, or parity. None of these variables were independently associated with bicarbonate or P_{CO_2}.

Comment

Controversy exists with regard to the effects of epidural anesthesia on the course of labor and the metabolic status of the newborn infant despite its widely accepted use. Some studies have shown a tendency toward mild fetal metabolic acidemia in labors with epidural analgesia to be less than that found in unanesthetized pregnancies,[13, 14] whereas others have found no differences.[15] Problems in interpreting the literature relate to the lack of standardization of methodology

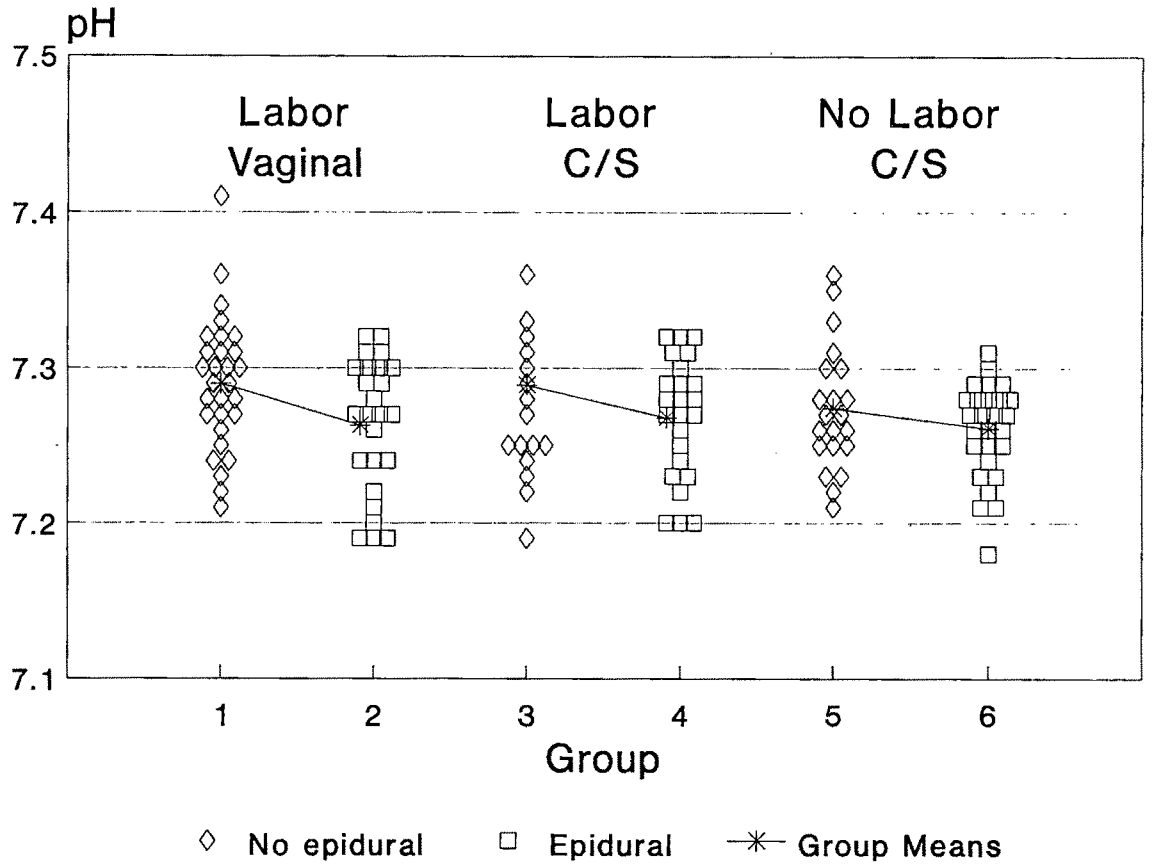

Fig. 1. Mean umbilical arterial pH values and distribution presented by group. A statistically significant difference was noted between groups 1 and 2 ($p < 0.05$, Student t test).

and patient characteristics, and technical improvements over time.

Gale et al.,[1] who studied a group of women who had elective and nonelective cesarean sections, found that epidural anesthesia offers neonatal advantages because the requirement for neonatal respiratory assistance was higher among women who received general anesthesia. However, mothers with high-risk complications were included in groups undergoing nonelective cesarean section, possibly confounding their results. They found no difference in mean acid-base values between the epidural and general anesthesia groups among those delivered electively, in accordance with our study. Their data indicated an increased need for neonatal respiratory assistance after general anesthesia for elective cesarean section. These results were not duplicated by our study, nor were they explained by their acid-base values, possibly indicating a direct effect of general anesthetic agents on newborn respiratory efforts. Ong et al.[2] demonstrated lower 1-minute Apgar scores in infants delivered by cesarean section with general anesthesia under elective conditions, and lower 1- and 5-minute scores, and greater requirements for intubation and artificial ventilation, in those delivered under general anesthesia in urgent conditions, compared with those delivered under similar conditions with regional anesthesia. Anesthetic technique did not affect perinatal survival.[2] Conversely, Fox et al.[4] found no difference in neonatal Apgar scores, funic acid-base values, or increased time to sustained respiration after elective cesarean section between infants delivered with epidural compared with general anesthesia, in accordance with our findings.

The mild reduction in funic acid-base values associated with epidural analgesia in the infants delivered vaginally was partially associated with an increased length of labor in the regional anesthesia group. Katz et al.[16] demonstrated a significant rise in lactate and decrease in pH in the umbilical artery, with increasing lengths of stage II labor over 15 minutes in women who had no anesthesia. These results have been confirmed by others.[17] Thorp et al.[18] demonstrated an increased length of labor and rate of cesarean section for dystocia in nulliparous women delivered with use of an epidural anesthetic.[18] We found a highly significant increase in the length of stage II labor in the group delivered vaginally who had epidural analgesia, which was independent of parity, and significance held for both nullipa-

rous and parous gravid women. Length of labor fully explained the lower pH in this group.

Another reason for relative hypoxemia and hypercarbia associated with the use of epidural analgesia is hypotension as a result of sympathetic blockade. Brizgys et al.[19] demonstrated a significant decrease in mean funic arterial pH values in women who experienced hypotension at cesarean section; however, the magnitude of this difference never exceeded 0.04 pH units. In our series transient symptomatic hypotension, as evidenced by the need for ephedrine, did not contribute to any funic acid-base changes. In no instance was maternal hypotension prolonged.

The indication for cesarean section and presence or absence of an epidural catheter at the time of the decision influenced the choice of anesthesia. Patients with arrested labor from cephalopelvic disproportion were more inclined to have regional rather than general anesthesia for cesarean section (96% vs 25%), whereas those undergoing cesarean section in the active phase of labor because of malpresentation of the fetus were more likely to have general anesthesia (37% vs 0%). The belief that use of epidural rather than general anesthesia is advantageous to the fetus contributed to the preponderance of epidural analgesia for elective repeat cesarean section in our institution.

In summary, analysis of funic acid-base determinations at birth demonstrates that use of epidural anesthesia offers no clear-cut advantage to the respiratory and metabolic status of the normal, term fetus. In fact, there were higher arterial P_{CO_2}, lower pH, and higher arterial bicarbonate values in patients with normal labor who were delivered vaginally with epidural anesthesia than in those without. The pH findings were explained by longer labors associated with epidural analgesia and were independent of parity. In women undergoing cesarean section in the active phase of labor, use of epidural anesthesia was associated with significantly lower arterial and venous P_{O_2} values compared with general anesthesia. These differences appear to be independent of length of labor or incidence of symptomatic hypotension. When the previously published normal ranges for funic acid-base values are considered, it is unlikely that these differences are clinically important for the term fetus with a normal electronic monitor pattern. For patients who had cesarean sections electively or before the active phase of labor, use of epidural anesthesia did not result in improved funic blood gas values when compared with general anesthesia.

Effect of uterine contractility and maternal hypotension on prolonged decelerations after bupivacaine epidural anesthesia

Ralph M. Steiger, MD,[a] and Michael P. Nageotte, MD[b]
Orange and Long Beach, California

Patients with prolonged decelerations after bupivacaine epidural anesthesia were matched with control patients. It was found that there were no differences in the decrease in mean arterial blood pressure after epidural anesthesia between those with prolonged decelerations (5 ± 9 mm Hg) and those without (5 ± 9 mm Hg). Uterine hypertonus was suggested as a cause in the prolonged deceleration group as a result of a higher rate of subjective impressions of uterine hypertonus (82% vs 11%) and more frequent use of terbutaline (30% vs 0%) after epidural anesthesia. With patients with internal uterine pressure monitors used as their own controls, it was also found that basal uterine tone was higher during periods when the deceleration occurred (26 ± 9 mm Hg) than when it did not (13 ± 4 mm Hg), and in comparison to windows before epidural anesthesia (12 ± 5 mm Hg). (AM J OBSTET GYNECOL 1990;163:808-12.)

Key words: Bupivacaine, epidural anesthesia, prolonged deceleration, maternal hypotension, uterine hypertonus

A prolonged fetal heart rate (FHR) deceleration after the administration of epidural anesthesia is an anxiety-producing event that may follow this common form of analgesia. This event has not generated the degree of investigation that occurred with FHR decelerations after paracervical blocks for pain relief in labor. The frequency of prolonged decelerations after bupivacaine epidural anesthesia has been reported by Vroman et al.,[1] and Abboud et al.[2, 3] as between 7.9% and 12.5%. Abnormal FHR patterns have been noted to be more common with use of bupivacaine than chloroprocaine or lidocaine.[3] The incidence of prolonged decelerations after paracervical blocks with bupivacaine is higher (23%[4]) and is contraindicated for this technique.[5] The exact mechanism responsible for these potentially serious changes in FHR has not been clearly delineated. In this study the association of prolonged decelerations after intrapartum bupivacaine epidural anesthesia with changes in uterine activity and the lack of an association with changes in maternal blood pressure is reported.

Material and methods

This retrospective, case-controlled study was conducted at Long Beach Memorial Women's Hospital, an obstetric tertiary care center in southern Los Angeles County.

Patients with prolonged decelerations constituted the study group. Between July 1, 1988, and July 1, 1989, patients were identified by nursing staff and physicians, and their names were forwarded to the first author. For the year 1987, a computerized search was made of the hospital data base of obstetric patients, cross-referencing the diagnosis of fetal bradycardia with epidural anesthesia. Eligibility criteria included a prolonged deceleration with a decrease of the FHR below 120 beats/min for at least 2 minutes' duration within 1 hour of the completion of the initial loading dose of 0.25% bupivacaine epidural anesthesia. Twenty-seven patients were selected for study. Twelve had internal uterine pressure catheters. Subjects were rejected primarily for poor-quality FHR tracings or the use of anesthetic agents other than bupivacaine.

The interpretation of hypertonus as abnormal basal uterine tone was subjective; however, the following guidelines were used. An elevation of basal uterine tone of ≥10 mm Hg between contractions on two or more consecutive intervals, compared with prior intervals, was considered to have clinical significance. This degree of change was also used for patients with external monitors even though it is acknowledged that this amount of change is only relative and not absolute.

Each patient of the study group was matched by age (±3 years), parity, and gestational age (±4 days) with two control patients who had bupivacaine epidural anesthesia during labor without prolonged decelerations. The control subjects were selected randomly from the delivery logbooks of 1987 and 1988. Patients who had epidural anesthesia for cesarean section only were excluded from the control group. Each of the twelve patients in the study group with internal uterine pressure catheters was matched with at least one control patient who also had an internal uterine pressure catheter

before and after the administration of epidural anesthesia.

Bupivacaine 0.25% was the most commonly selected epidural agent and was used in all study and control group patients. Prehydration with 500 to 1500 ml of isotonic fluids was given in all procedures. Epidural catheters were placed with the women in the sitting position in all but three patients in the study and control groups. The three patients who had catheters placed while on their sides were in the study group with prolonged decelerations. Epidural anesthetics were given as an initial dose of 9 to 14 ml (12.4 ± 0.9 ml) of 0.25% bupivacaine. In all cases a test dose of 2 to 4 ml was given before the remainder of the initial dose. Epinephrine was not used in any of the anesthetic solutions. In three cases patients who had not received adequate relief by 20 minutes received another injection of 5 ml. In the study group this occurred with one patient at 23 minutes and was immediately followed by a prolonged FHR deceleration at 24 minutes. Two patients in the control group received a similar dose at about the same time. One was followed by a solitary late deceleration. The total time required to place the epidural catheter and administer the initial dose of bupivacaine was usually <15 minutes. Administration of the anesthetic agent from test dose to final dose usually required 5 minutes. After the initial dose of bupivacaine was given the patient was placed on her side and given a continuous infusion of 4 to 7 ml/hr (5.9 ± 0.9 ml) of 0.25% bupivacaine. The patient was then moved from one side to the other to ensure a uniform block. Blood pressure recordings were taken by the nursing staff with a sphygmomanometer with the patient either on her side or supine with a wedge. Blood pressure was converted to mean arterial pressure, calculated as the diastolic pressure plus one third of the difference of systolic and diastolic pressure. Recordings were made before the procedure and at 5-minute intervals after epidural anesthesia for 25 minutes, then at 15 minutes, and then at 30-minute intervals.

Data for this study were obtained from maternal charts and FHR strips. The study focused on uterine activity, FHR, and blood pressure during the hour before and after administration of the epidural anesthesia. The time of epidural anesthesia was determined as the last injection of the initial dose of bupivacaine as noted on the FHR monitor strip. This 2-hour period of the FHR strip was divided into 10-minute windows, 6 minutes before and 6 minutes after the initial dose. Data on FHR, deceleration patterns, uterine activity, medications, blood pressure, and cervical change were recorded for each 10-minute window. Patients with internal uterine pressure catheters had uterine activity recorded as Montevideo units (peak contraction pressure minus the average basal tone before and after the contraction) and basal uterine tone (the nadir of uterine pressure between contractions averaged for the window). Only the number of contractions per 10 minutes was recorded for patients with external monitors. Patients who had epidural anesthesia for cesarean section only were not specifically excluded but none were detected with prolonged decelerations after anesthesia administration. This may be because they were monitored for only a short time after catheter placement.

Statistical tests included χ^2, Fisher's exact test, paired t test, and Wilcoxon ranked-sum test, as appropriate for the given instance. Calculations of Fisher's exact test and Wilcoxon ranked-sum test were done with the BMDP Program (Program 3D/3S, 1988, Westwood, Calif.). Data were considered statistically significant at the $p < 0.05$ level. All tests were two-sided. All variances expressed in this article are expressed as 1 SD.

Results

The frequency of prolonged decelerations after bupivacaine epidural anesthesia was estimated at 8.5%, based on the random sampling of patients selected for control subjects. This estimate is conservative as patients with this phenomenon had already been removed from the sample as described previously. There were five patients who were rejected as control subjects because of the presence of a prolonged deceleration after epidural administration.

The similarities in the two groups of patients are summarized in Table I. There were no significant differences in birthweights, number of cesarean sections, or use of oxytocin. High-risk factors were rare in both groups. There were two patients with hypertensive disorders in the control group and one in the deceleration group. Overall uterine activity, measured by Montevideo units, was higher in the deceleration group (Table II). When only uterine activity before epidural anesthesia was compared this difference lost its statistical significance. The control group labored longer after epidural administration than the study group. There were no differences between the two groups in initial anesthetic doses or in the rate of the continuous infusion. None of the patients with prolonged decelerations or in the control group experienced seizures or signs of intravenous injection after the administration of the epidural anesthetic. Patients were nulliparous 70% of the time in both groups.

The prolonged decelerations occurred at an average of 13.3 ± 9.6 minutes from the end of the initial dose of epidural anesthetic and lasted an average of 6.6 ± 2.9 minutes. The average decrease in FHR was 64 ± 15 beats/min from a baseline of 129 ± 9 beats/min.

Blood pressure. Blood pressure measurements were taken during the prolonged deceleration in 63% of the study group and averaged 77 ± 7 mm Hg. The average mean arterial pressure during the deceleration did not

differ significantly from the average mean arterial pressure in the hour after epidural anesthesia (77 ± 8 mm Hg). The statistical comparison of these two groups is sufficiently powerful to have an 80% probability of detecting a difference of 7 mm Hg. Blood pressure comparison between patients with prolonged decelerations and controls are summarized in Table III. Mean arterial pressure changed an average of 5 mm Hg with epidural anesthesia in both the patients with prolonged decelerations and the control patients without these decelerations. However, there was no significant difference beteen the two groups. The data were sufficiently powerful to have an 80% probability of detecting a difference of 13 mm Hg. There was also no significant difference between the two groups in the number of patients who had a 10% to 20% decrease in blood pressure measurements. There were no patients in either group with ≥30% decrease in mean arterial pressure. Ephedrine was used only once in the control group and never in the study group.

Uterine activity. Patients with prolonged decelerations after epidural anesthesia were significantly more likely to have a subjective impression of uterine hypertonus (14/17 vs 6/54, $p < 0.05$, χ^2). There were 10 patients with external tocometry in the deceleration group who were not included in these numbers because of an absence of recorded contractions at the time of the prolonged deceleration. A significant difference was found in the women who received terbutaline (8/27 vs 0/54, $p < 0.05$, Fisher's exact test) after epidural anesthesia. Patients with prolonged decelerations and an internal uterine pressure catheter were also more likely to have received terbutaline than those with prolonged decelerations and external monitors (6/12 vs 2/15), but this did not achieve statistical significance.

Attempts to quantitatively identify patients with increased uterine activity or hypertonus were surprisingly difficult. Data from external tocometry were generally not helpful. Analysis of data from internal uterine pressure catheters was more helpful. With the patient serving as her own control, it was noted that basal uterine tone was significantly more elevated in windows when the prolonged deceleration took place compared with the other windows in which there was no prolonged deceleration (26 ± 9 vs 13 ± 4 mm Hg; $p < 0.05$, paired t test). This was also true if the windows preceding administration of epidural anesthesia were used for comparison (26 ± 9 vs 12 ± 5 mm Hg; $p < 0.05$, paired t test). Similar analyses of Montevideo units also showed an increase, but this did not achieve statistical significance. Uterine pressure during hypertonic contractions can exceed the scale on the FHR tracing, thus making this analysis difficult (Fig. 1).

There were statistically significant differences in the average 5-minute Apgar scores. These differences were so small however, that it is doubtful that they are of clinical significance. The difference in Apgar scores <7 at 1 and 5 minutes was not significant. Among the four infants with Apgar scores <7 at 1 minute, all were delivered at least 1 hour after administration of epidural anesthesia or prolonged deceleration. Conversely, none of the nine infants born within 1 hour of administration of epidural anesthesia or the end of the prolonged deceleration had an Apgar score <7 and only two had scores of 7.

Comment

The cause of prolonged decelerations after administration of epidural anesthesia has not been clearly established. Cibils[6] and Gibbs and Noel[7] demonstrated the ability of anesthetic agents to cause uterine artery

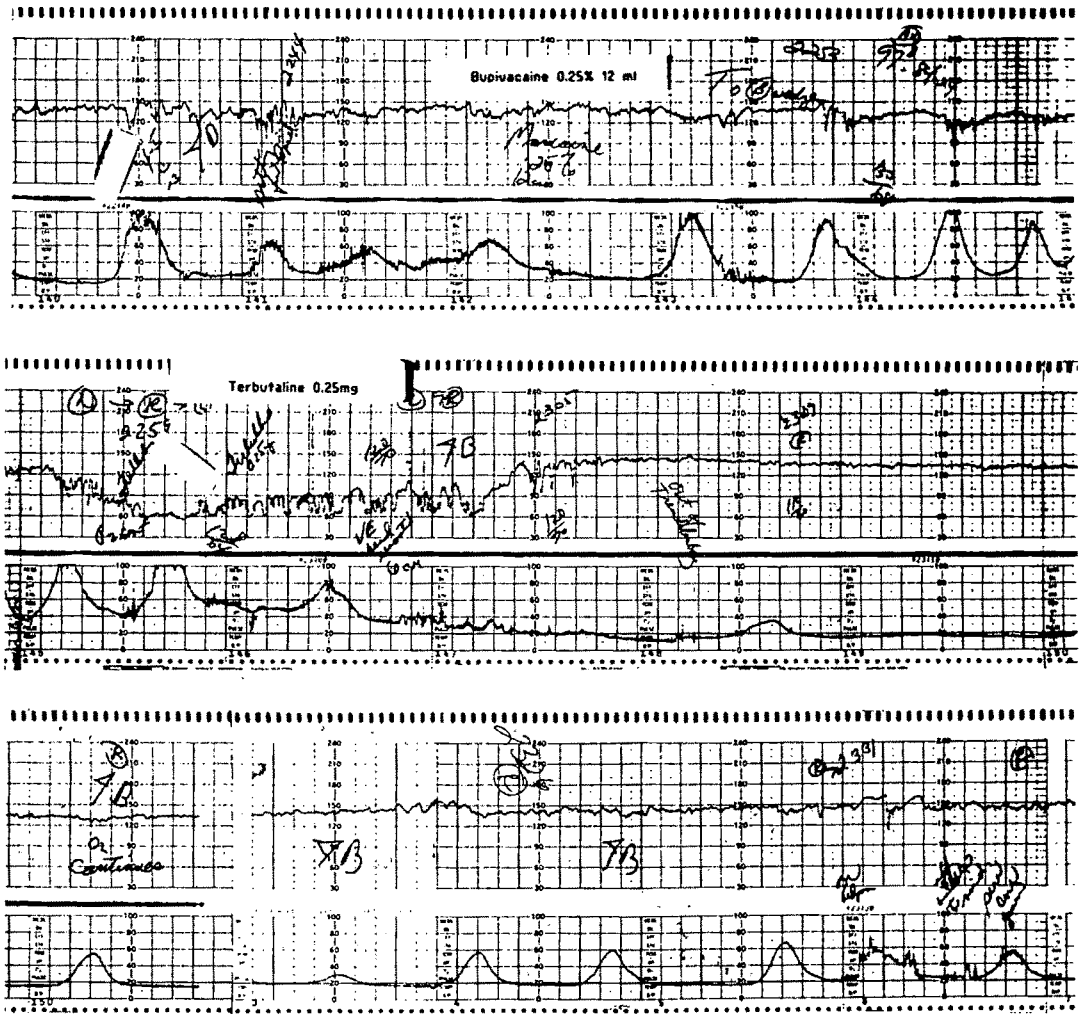

Fig. 1. A representative example of a patient with an internal uterine pressure catheter and a prolonged fetal heart rate deceleration after bupivacaine epidural anesthesia.

constriction in vitro. Fishburne et al.,[8] in their work with chronic preparations of fetal lambs, found that anesthetic agents that include bupivacaine stimulate vasoconstriction of uterine and placental vessels. They also found an increased uterine contractility and tone which, in turn, decreased uteroplacental blood flow. This decrease in uterine blood flow would precede the uterine contractions; they concluded that the uterine artery vasoconstriction was independent of uterine contractility.

The question of decreased uterine blood flow occurring after bupivacaine epidural anesthesia has been addressed in vivo in human Doppler flow studies.[9, 10] These studies show no change or improvement in the systolic/diastolic ratios, but none of the studies included a fetus with a FHR deceleration. Furthermore, all patients in the two studies underwent elective repeat cesarean section and none were in labor.

Vroman et al.,[1] in their series of 126 patients who had induction of labor with amniotomy and oxytocin, found that uterine hypertonus was associated with prolonged decelerations in seven of 10 patients with this problem after bupivacaine epidural anesthesia.

Schifrin[11] found that the risk of pathologic FHR patterns and hypertonus after lidocaine epidural anesthe-

sia was increased by the concomitant use of oxytocin. This observation could not be reproduced in our study. There was no difference in the frequency of oxytocin use in the prolonged deceleration group compared with control subjects.

The results of our study suggest that uterine hypertonus is, in fact, correlated significantly with the presence of prolonged FHR decelerations after bupivacaine epidural anesthesia. Blood pressure changes were not associated with patients with prolonged decelerations. The observed changes in mean arterial pressure in the deceleration group were actually quite similar to those in the control group. It is recommended that in the treatment of the fetus with a prolonged deceleration after epidural anesthesia that strong consideration be given to the use of a rapid-acting tocolytic agent such as terbutaline, particularly in patients with external monitors, in whom an accurate assessment of uterine activity can be nearly impossible. The presence of prolonged decelerations after bupivacaine epidural anesthesia appears to have minimal, if any, effect on immediate fetal outcome.

We thank Wendy Dorchester for assistance with the statistical analysis and Lanie M. Adamson for editorial support.

The effect of amnioinfusion on uterine pressure and activity: A preliminary report

Marvin D. Posner, MD, Susan A. Ballagh, MD, and Richard H. Paul, MD
Los Angeles, California

Transcervical intrapartum amnioinfusion of normal saline solution is being used in a number of centers. Over the past few years indications for the procedure have included prophylaxis and treatment of intrapartum decelerations in both term and preterm gestations, dilution and lavage of meconium-stained amniotic fluid, and for direct administration of antibiotics within the amniotic cavity in cases of chorioamnionitis. Little is reported about the real or potential risks of this procedure to both the mother and fetus. Over the past 2 years we observed several isolated cases of increased uterine activity by palpation coupled with fetal distress during amnioinfusion. These instances prompted us to study in a systematic fashion the relationships between uterine tone and activity during intrapartum amnioinfusion. We measured uterine tone and quantitated uterine activity in 10 patients undergoing intrapartum amnioinfusion and compared values 20 minutes before, during, and 20 minutes after amnioinfusion. A significant increase in uterine tone ($p < 0.05$) was noted during and after the infusion. No difference in uterine activity was observed in any of the study periods. A case of uterine hypertonus and fetal bradycardia and a suggested procedure scheme for intrapartum amnioinfusion are presented. (AM J OBSTET GYNECOL 1990;163:813-8.)

Key words: Amnioinfusion, uterine tone, uterine activity

Amnioinfusion has been used with increasing frequency during the intrapartum period over the past few years. The technique has been primarily used to decrease or relieve variable decelerations during labor.[1-3] Additional studies have addressed the use of this technique in preterm premature rupture of membranes,[4] meconium-stained amniotic fluid,[5, 6] and intrauterine infection therapy with direct antibiotic instillation.[7]

In the first prospective randomized clinical trial with amnioinfusion Miyazaki et al.[2] described a significant decrease in variable decelerations in the amnioinfused group (51%) versus the noninfused group (4.2%). This was most significant in the nulliparous patients with relief noted in 66.7% of the amnioinfusion group versus 0% in the noninfusion group. There was also a significant decrease in the rate of cesarean section in these patients for fetal distress, 14.8% in the infusion group versus 47.8% in the noninfusion group.

In a randomized trial of amnioinfusion versus controls in preterm premature rupture of the membranes, Nageotte et al.[4] showed both a statistically significant difference in the incidence of all variable decelerations during the first stage of labor (2.4% versus 7.9%) and a significant decrease in severe variable decelerations during the second stage of labor in the amnioinfusion group as compared with controls (2.9% versus 10.1%). They also showed a significant difference in pH values between the treated and control groups.

A recent publication by Wenstrom et al.[5] described a successful decrease in the incidence of low 1-minute Apgar scores, meconium noted below the cords, and of operative deliveries with saline solution amnioinfusion in the presence of meconium-stained amniotic fluid. Similarly, Sadovosky et al.[6] reported an incidence of thick meconium noted at delivery of 5% in amnioinfused patients versus 62% of controls. In patients who had intrapartum amnioinfusion their fetuses also had a decreased incidence of acidosis (16% versus 38%) and meconium noted below the cords (29% versus 0%) as compared with controls.

Although the procedure of amnioinfusion with normal saline solution is generally believed safe, potential complications must be considered. Gimbel[8] posed the question of an increased incidence of umbilical cord prolapse after amnioinfusion; however, no substantiative reports have emerged.

An additional consideration relates to the potential occurrence of uterine hypertonus as a result of stretching of the myometrial muscle fibrils, which in turn causes increased passive tension. This theoretical effect coupled with clinical observations that suggest increased uterine tonus is most pertinent given a potentially compromised fetus or a patient with a prior uterine scar. Miyazaki[2] noted an "artificial increase" in the

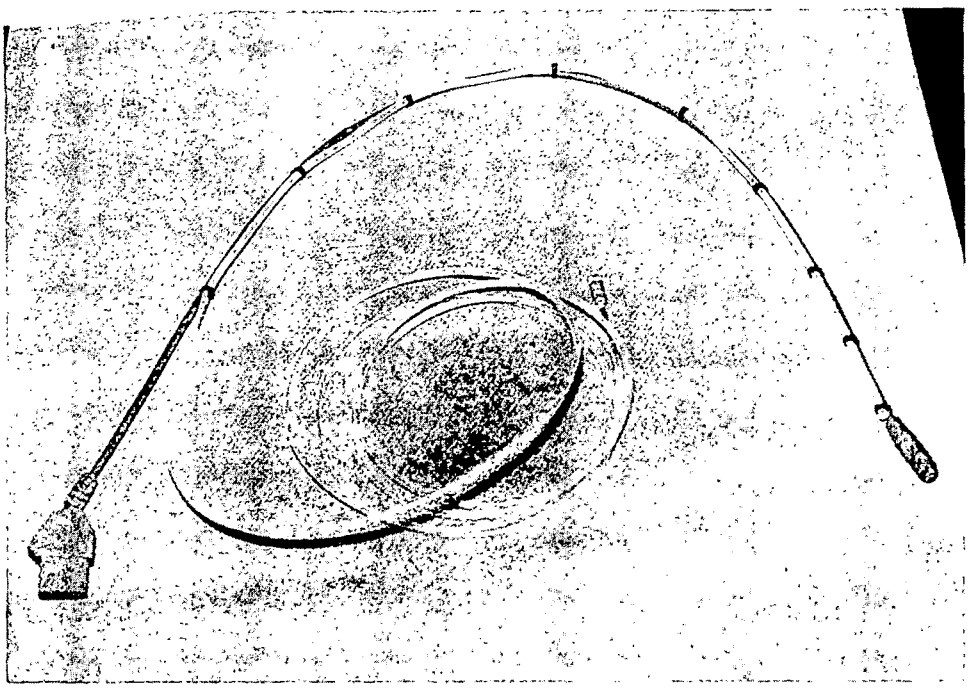

Fig. 1. Study device consisted of conventional fluid-filled intrauterine pressure catheter attached with heat-shrinkable tape to commercially available pressure-tipped intrauterine sensing device (Laurel Medical, Northfield, Minnesota).

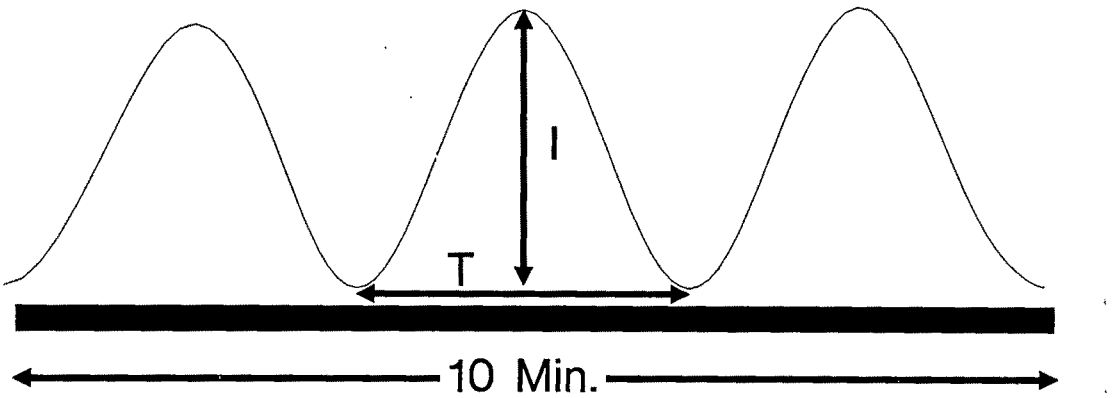
resting tone of the uterus and attributes this "artificial increase" to resistance to outflow of the infusate through the holes of the catheter. Evaluation of the technique and existent data preclude a clear answer with regard to uterine tone.

The purpose of this study was to evaluate the effects, if any, on the uterine tone and activity associated with intrapartum transcervical amnioinfusion.



Material and methods

Patients were selected for amnioinfusion on the basis of any one or combination of the following criteria. Decreased amniotic fluid volume on the basis of amniotic fluid index of <5.0 cm, the presence of moderate to severe variable decelerations refractory to position changes, or the presence of meconium-stained amniotic fluid. Ten intrapartum patients with ruptured membranes, undergoing continuous direct fetal heart rate (FHR) monitoring, and deemed suitable for the insertion of an intrauterine pressure catheter were studied.

All patients had amniotic fluid volume assessed by the four-quadrant technique described by Rutherford et al.,[9] both before and immediately after the amnioinfusion. The infusion-study device consisted of a standard intrauterine pressure catheter attached with heat-shrinkable tape to a pressure-tipped sensor transducer, both of which are commercially available (Fig. 1). Normal saline solution, 250 ml warmed to 37° C was infused through the intrauterine pressure catheter by gravity flow.

The patient was prepared and draped for vaginal examination and the pressure-tipped device was zeroed to atmospheric pressure before insertion. After insertion of the study device the resting tone of the uterus was measured. The basal tone of the uterus as measured by the fluid-filled catheter was matched to that of the pressure-tipped catheter. For a period of 20 minutes before the infusion, the uterine activity from both systems was recorded on both a paper strip chart and on a multichannel tape recorder. After the 20-minute observation period the intrauterine pressure catheter was disconnected and the infusion of 250 ml warmed normal saline solution was begun. During the amnioinfusion, uterine tone and activity was continuously monitored with the pressure-tipped sensing device. After the infusion, the intrauterine pressure catheter was reconnected and the uterine activity was recorded for 20 minutes.

The uterine tone was measured in millimeters of mercury (mm Hg) and overall uterine activity was measured and expressed in Alexandria units[10] for the three study periods. Alexandria units are the average intensity of contractions, multiplied by the frequency of con-

Average I X Frequency / 10 min. X Average Duration (min.)

Fig. 2. Alexandria units are a qualitative unit of measurement of uterine activity. Alexandria unit = Average intensity *(I)* × Contraction frequency per 10 minutes × Average duration (in minutes) of contractions.

tractions in a 10-minute period, multiplied by the average duration of the contractions (Fig. 2).

Analysis of variance with subsequent Tukey-A and Tukey-B post hoc comparison was used for evaluation of both the uterine tone and uterine activity expressed in Alexandria units for the 20-minute preinfusion, during the infusion, and the 20-minute postinfusion time periods. Significance was reached with a value of $p < 0.05$.

Results

A statistically significant increase ($p < 0.05$) was noted comparing the preinfusion period uterine tone with that observed during the infusion period. Significance ($p < 0.05$) was also found in comparing preinfusion period uterine tone with that of the postinfusion period. The comparison of uterine tone during the infusion period with that of the postinfusion period showed no difference (Fig. 3).

The comparison of uterine activity, expressed in Alexandria units for all study periods failed to show significance at the $p < 0.05$ level (Fig. 4).

Additional observations noted from review of the data showed an average increase in the amniotic fluid infusion of 4.6 ± 1.8 cm for each 250 ml of sterile saline solution infused. The average time required for infusion of 250 ml was 24.6 ± 10.4 minutes. The range of time was 16.2 to 50.7 minutes.

There was a single notable complication observed during this limited evaluation in 10 study subjects. One patient had an episode of uterine hyperactivity soon after the amnioinfusion was begun. This was associated with a prolonged FHR deceleration. Both abnormalities seemingly responsed to intravenous administration of magnesium sulfate. The patient was taken to the operating room for emergency cesarean delivery but on reevaluation the uterus relaxed and the FHR had become normal. Fifteen hours later a 3540 gm male infant was delivered by vacuum extraction with Apgar scores of 9 at both 1 and 5 minutes (Fig. 5).

Comment

In recent years there has been an increasing interest in transcervical intrapartum amnioinfusion. Present indications include prophylaxis and treatment of intrapartum decelerations in both term and preterm gestations,[1-4] dilution and lavage of meconim-stained amniotic fluid,[5,6] and for direct administration of antibiotics within the amniotic cavity in cases of chorioamnionitis.[7] In the limited number of current reports that describe amnioinfusion, little has been reported with regard to potential morbidity to either the mother or fetus.

Clinicians performing amnioinfusion must be aware of the theoretical and potential risks associated with this procedure. When asked by Gimbel[8] about the possibility of cord prolapse, Miyazaki responded that the incidence of this potentially devastating complication was actually one half that seen in vertex presentations during normal labor. We were unable to document other reports of this complication. In our institution over the past year we have noted several instances of fetal dis-

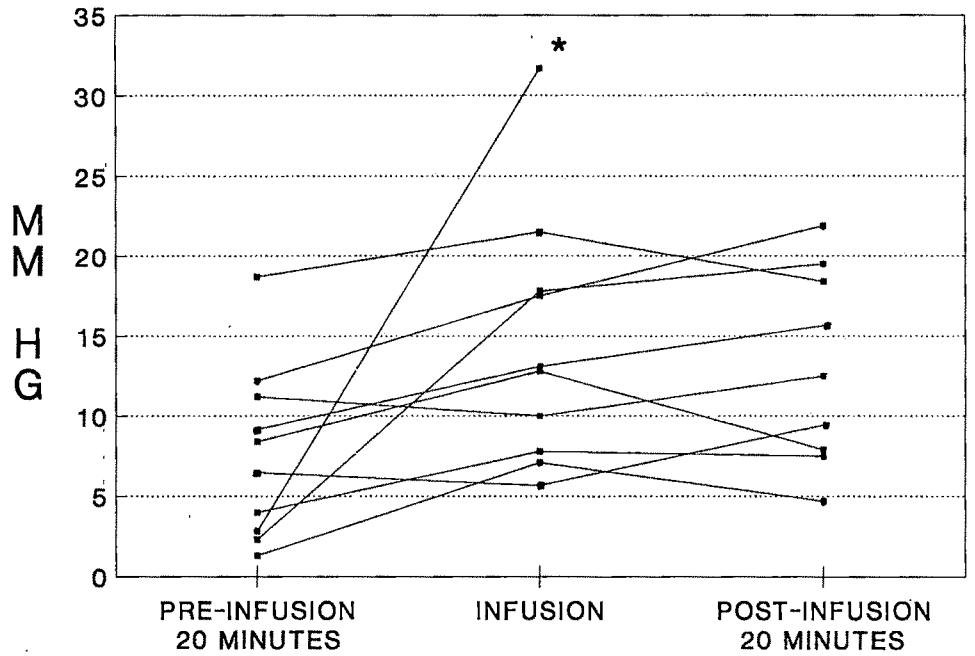


Fig. 3. Basal uterine tone in mm Hg for three study periods. *Asterisk* (*) identifies patient who experienced hypertonic episode followed by fetal distress (see Fig. 5).

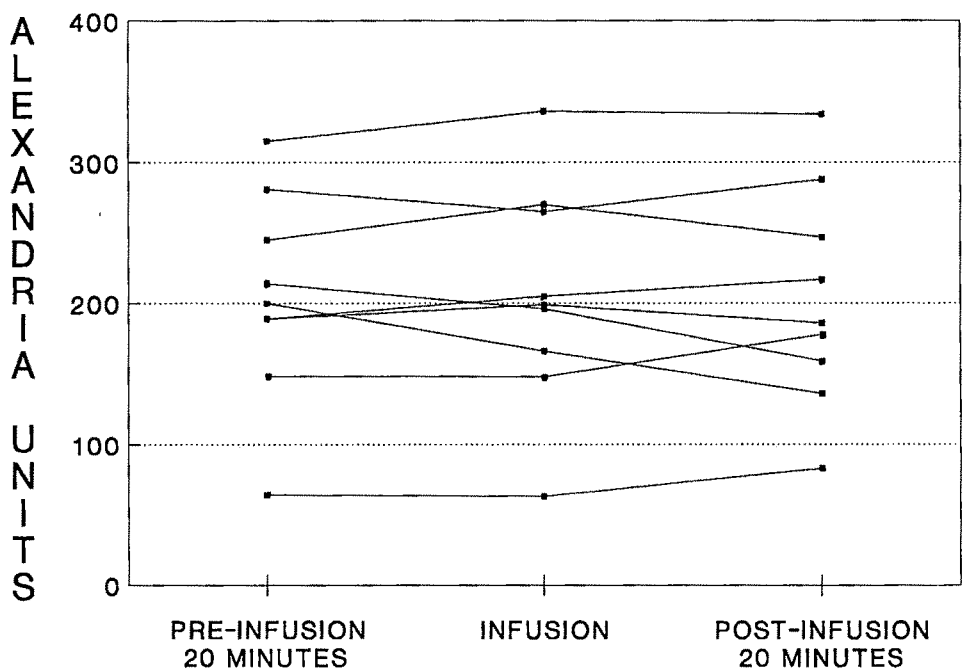

Fig. 4. Uterine activity as expressed in Alexandria units for three study periods.

tress during amnioinfusion. These were associated with a picture that suggests increased uterine activity with clinical palpation. These findings prompted us to better document such occurrences and perhaps define their cause.

Previously Tabor and Maier[11] reported a case of polyhydramnios and elevated uterine pressure during amnioinfusion. According to their report, 4300 ml of normal saline solution was transcervically amnioinfused over a 21-hour period. Some of the fluid leaked out of

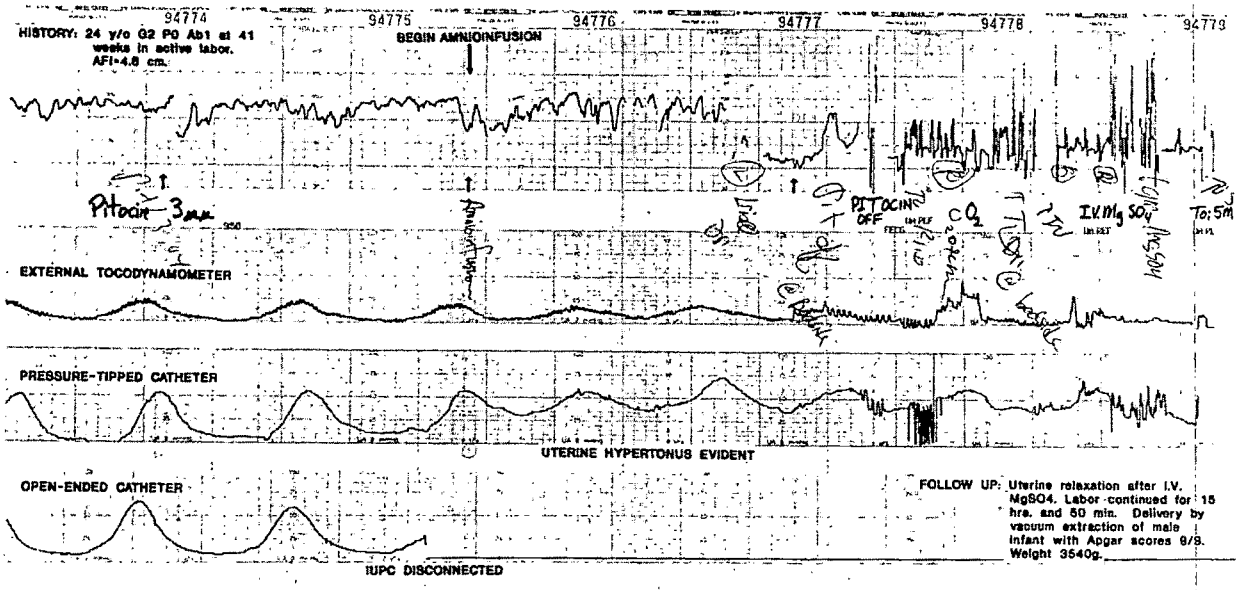

Fig. 5. FHR tracing for patient who experienced uterine hypertonus soon after amnioinfusion was begun. Uterine activity was recorded from external tocodynamometer, pressure-tipped catheter, and open-ended fluid-filled catheter. Patient history and outcome are reported.

the uterus but the majority remained. No estimation of the fluid volume was performed until fetal bradycardia was present. At that time the intrauterine resting pressure had increased to 50 mm Hg from 10 mm Hg before infusion. The FHR returned to normal only after subcutaneous terbutaline administration and removal of 900 ml of fluid. It was speculated that the increased intrauterine pressure had decreased uteroplacental perfusion that resulted in the fetal bradycardia.

Even with a small 250 ml volume of infusate our results show a statistically significant difference in the basal uterine tone when comparing preinfusion with infusion and postinfusion periods. We observed one case in which the uterine tone became excessive. This occurrence in one of 10 patients with the associated abnormal FHR findings is reason for concern and requires further investigative study. To that end an optimal approach to intrapartum amnioinfusion appears to be one in which either two intrauterine pressure catheters or a dual lumen catheter is used. Intrauterine pressure can thus be monitored at all times during the infusion. In addition some objective assessment of amniotic fluid volume should be performed before and at regular intervals after the infusion. In those facilities where such an approach is impractical, amnioinfusion may also be considered beneficial. The minimally acceptable approach in such instances would seemingly demand palpation of the uterus during infusion and close scrutiny of fetal well-being as judged by FHR.

In our institution we currently perform concomitant direct intrauterine pressure monitoring during the amnioinfusion. In addition we measure the amniotic fluid infusion of each patient before and immediately after the amnioinfusion. We attempt to achieve an amniotic fluid infusion of ≥8.0 cm and our infusion volumes are limited. An amniotic fluid infusion ≥8.0 cm was chosen as an objective postinfusion value because it is above our 5.0 cm "at risk" value and it also is well above the range of interobserver error of ±2.0 cm as reported by Rutherford et al.[12] Estimated infusion volume is calculated according to the observations of Strong et al.,[13] substantiated in this limited study, in that 250 ml of infusate will increase the amniotic fluid index by approximately 4 cm. With this method we should minimize the risk of polyhydramnios and overdistention of the uterus.

Further investigation will more accurately define the frequency of complications and probable major benefits for both the fetus and mother of this emerging intrapartum therapy.

Comparison of umbilical artery pH and 5-minute Apgar score in the low-birth-weight and very-low-birth-weight infant

Craig F. Stark, MD, Ronald S. Gibbs, MD, and Walter L. Freedman, MD
Denver, Colorado

The division between "normal" and low Apgar scores is based largely on data obtained from term newborns and may not apply to the premature infant. Umbilical artery pH has been suggested as a better indicator of intrapartum asphyxia. We examined the charts of 558 infants with birth weights ≤2500 gm with respect to umbilical artery pH, 5-minute Apgar scores, and birth weight percentiles. A positive correlation between birth weight and 5-minute Apgar score was noted. No such relationship existed between birth weight and umbilical artery pH. Within birth weight groups, small-for-gestational-age infants have higher Apgar scores and lower umbilical artery pH values than their appropriate-for-gestational age counterparts. (AM J OBSTET GYNECOL 1990;163:818-23.)

Key words: Low birth weight, very low birth weight, acid-base status, Apgar scores

The Apgar score was introduced in the early 1950s to assess, compare, and discuss the results of obstetric practices, types of maternal pain relief, and the effects of resuscitation on the newborn.[1] Although Apgar scores <7 at 5 minutes may implicate the presence of intrapartum asphyxia, most of these infants are vigorous and exhibit no other evidence of an asphyxial insult.[2,3] Umbilical arterial pH may be a more reliable indicator of perinatal asphyxia, but no agreement exists on a value to distinguish normal from abnormal. Most published data on Apgar scores and pH have studied term newborns. Extrapolation of these data to low birth weight (≤2500 gm) and very low birth weight (≤1500 gm) may not be appropriate. We surveyed the charts of all infants delivered at our institution over a 25-month period with birth weights between 500 and 2500 gm to evaluate the relationships between birth weight, 5-minute Apgar scores, and umbilical pH. We subsequently divided the study population into small-for-gestational-age and appropriate-for-gestational-age groups to determine if differences existed between them when either umbilical artery pH or 5-minute Apgar scores were considered.

Methods and material

On Oct. 1, 1987, it became standard policy at Denver General Hospital to obtain umbilical cord blood samples on all newborns for blood gas analysis. The samples were obtained by double clamping a section of umbilical cord immediately after delivery of the infant. Blood was drawn into a preheparinized syringe and analyzed within 30 minutes on a Corning 178 blood gas analyzer.

Gestational age was calculated with one of the following: (1) last mentrual period if the patient reported regular menses, had a pelvic examination in the first trimester, and had not used oral contraceptives within 2 months before conception, (2) obstetric ultrasonography if performed before 24 weeks or, if neither of these are available, (3) neonatal assessment of gestational age was determined with the Lubchenco method

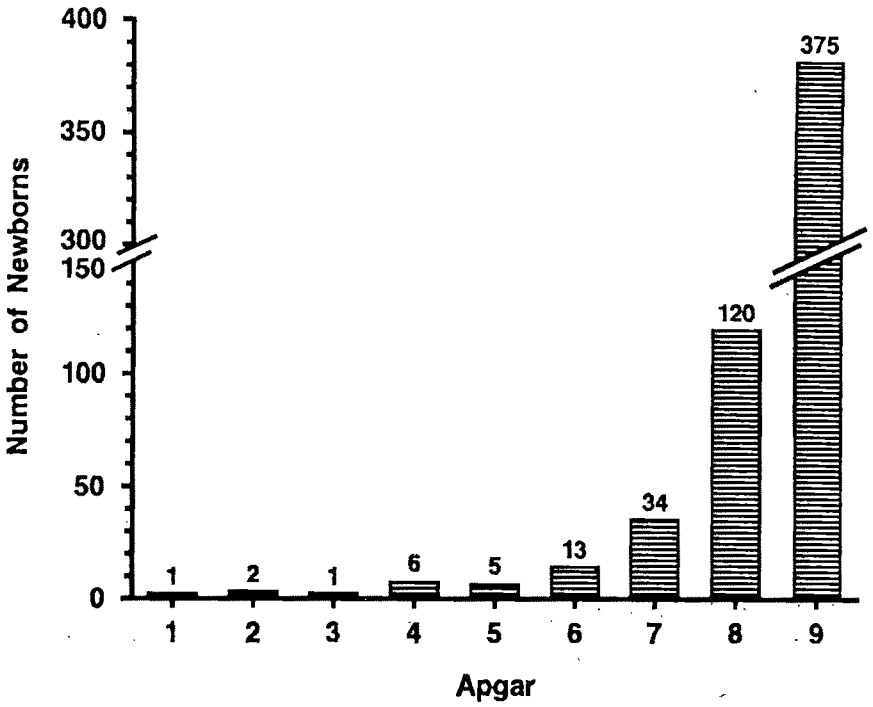

Fig. 1. Number of newborns for each 5-minute Apgar score.

at 1 hour and 24 hours of age.[4] If gestational age derived from the last menstrual period differed by more than 2 weeks from ultrasonographic or neonatal-assessment–based estimates, the latter were accepted as more accurate.

Assessment of birth weight percentiles was based on Denver newborn weight curves.[5]

Apgar scores were assigned to all live-born infants by either pediatric staff or labor and delivery nursing staff.[1]

The charts for all low-birth-weight infants born between Oct. 1, 1987, and Oct. 31, 1989, were reviewed. If a mother was delivered of more than one low-birth-weight infant during the study period, only the first infant was included in the analysis. Twin gestations and infants with chromosomal or major congenital anomalies were excluded.

Statistical analysis was performed with the SAS statistical package. Both umbilical artery pH and Apgar score data were analyzed as continuous variables to detect trends. Statistical tests included simple linear regression, one-way analysis of variance, and Fisher's exact t test. Statistical significance was defined as values of $p < 0.05$.

Results

Five hunded fifty-eight charts were reviewed. No 5-minute Apgar score was recorded in one case and no umbilical artery pH value was recorded for 40 infants. Fig. 1 displays the number of individuals assigned to each Apgar score value. No newborn in the study population was assigned a 5-minute Apgar score of 10. In Tables I and II the distribution of Apgar score and umbilical artery pH among the low-birth-weight and very-low-birth-weight groups is displayed. In Fig. 2, the relationship of 5-minute Apgar score to birth weight is plotted. An analysis of variance demonstrated a significant relationship between birth weight and 5-minute Apgar score ($p < 0.0001$). Mean Apgar scores were calculated for both the low-birth-weight (1501 to 2500 gm, 8.58 ± 0.87) and very-low-birth-weight (500 to 1500 gm, 6.96 ± 1.79) groups and these were significantly different from one another ($p < 0.0001$). In the very-low-birth-weight group, 34.8% of the infants had 5-minute Apgar scores <7 compared with only 2.5% in the low-birth-weight group. This difference was highly significant ($p < 0.0001$). Birth weights in the very-low-birth-weight and low-birth-weight groups were

≤7.51	0	1

then subdivided into small-for-gestational-age and appropriate-for-gestational-age groups. Mean Apgar scores were calculated and compared (Fig 3). The differences between mean Apgar scores in the small-for-gestational-age and appropriate-for-gestational-age groups were highly significant ($p < 0.006$) in both the last menstrual period and very-low-birth-weight groups. Umbilical artery pH values were then plotted against birth weight (Fig. 4). Linear regression analysis revealed no relationship between the two variables. When umbilical artery pH in newborns with 5-minute Apgar scores <7 were compared with infants with scores ≥7 (7.28 ± 0.13, vs 7.31 ± 0.07) no statistical difference was shown. Linear regression analysis was also used to describe the relationships between birth weight and both umbilical artery pH and 5-minute Apgar score in infants categorized as either small for gestational age or appropriate for gestational age (Figs. 2 and 4). Significant intergroup differences (small for gestational age versus appropriate for gestational age) were demonstrated in the relationship of umbilical artery pH and 5-minute Apgar scores to birth weight when both the slopes and the elevations of the two lines were compared ($p < 0.05$).

Comment

Of the five categories assessed in the Apgar score, four (heart rate, respiratory rate, reflex irritability, and muscle tone) are dependent on the maturity of both the central nervous and musculoskeletal systems for maximal score assignment.[1] During the last 3 months of fetal life continuous maturation of the cerebral cortex results in improvements in muscle tone and the appearance of reflexes used in Apgar score determinations.[6] Respiratory patterns constantly change dur-

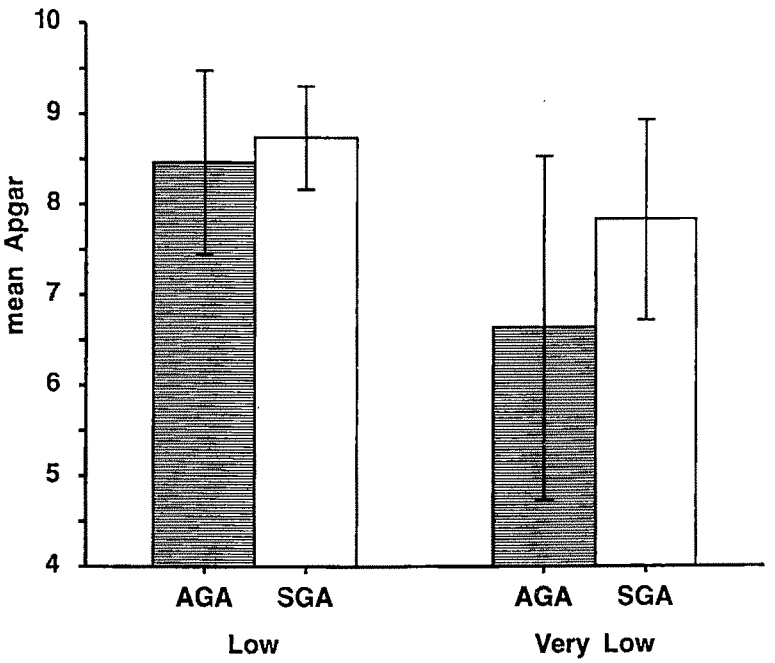

Fig. 3. Comparison of Apgar scores at 5 minutes (mean ± SD) in appropriate-for-gestational-age and small-for-gestational-age newborns in low- and very-low-birth-weight groups.

ing the last 2 months of fetal life, and periodic breathing and short periods of apnea account for a large proportion of respiratory activity. Respiratory patterns characteristic of term newborns are rarely observed before 23 weeks.[7, 8]

Several investigators have demonstrated the frequent occurrence of low Apgar scores in the nonacidemic premature infant.[2, 9-13] An immature central nervous system, musculoskeletal system, or both, rather than the presence of significant acidosis, appears to be the most important factor in the increased incidence of Apgar scores <7 in these infants. Not only did we confirm this relationship between low birth weight and Apgar scores <7 but we also expanded on it. We demonstrated a linear relationship between 5-minute Apgar scores and birth weight in newborns with birth weights <2500 gm. When we divided the study group into low-birth-weight (1501 to 2500 gm) and very-low-birth-weight groups (500 to 1500 gm) we found the influence of birth weight to be most clinically significant in the newborns with birth weights <1500 gm. Although other investigators have noted that 50% to 70% of very-low-birth-weight infants and from 8% to 18% of low-birth-weight infants have 5-minute Apgar scores <7,[12, 13] we found the incidence of these low Apgar scores to be significantly less than previously reported (very low birth weight, 34.78%; low birth weight, 2.54%). This finding may reflect a higher proportion of small-for-gestational-age or growth-retarded individuals in our very-low-birth-weight and low-birth-weight populations.

When compared with infants of similar low birth weight, we found that infants categorized as small-for-gestational-age had significantly higher 5-minute Apgar scores than their appropriately grown counterparts. Although debate exists regarding the use of the *t* test and analysis of variance to analyze Apgar score data, recent evidence appears to support its accuracy in this context (Bottoms S, unpublished data). We speculate that this is caused by a tendency of these infants to be older, growth-retarded, or both. Delivery of the very small infant often occurs in a setting in which little or no prenatal care has been obtained. These pregnancies are often complicated by the presence of obstetric and maternal conditions that are associated with uteroplacental insufficiency, subsequent intrauterine growth retardation, and delivery of a small-for-gestational-age infant. Neurologic investigations of low-birth-weight newborns led Amiel-Tison[6] to conclude that those infants who appeared to be growth retarded were more neurologically developed than was expected on the basis of birth weight alone. Growth retardation leads to a compromise in birth weight, but not at the expense of central nervous system or musculoskeletal system development. The differences between Apgar scores in these two groups (small-for-gestational-age group versus appropriate-for-gestational-age group) were most clinically apparent in the very-low-birth-weight group (Fig. 2). These observations reinforce the importance of central nervous and musculoskeletal system maturity rather than acidemia on 5-minute Apgar scores in the majority of small premature infants.

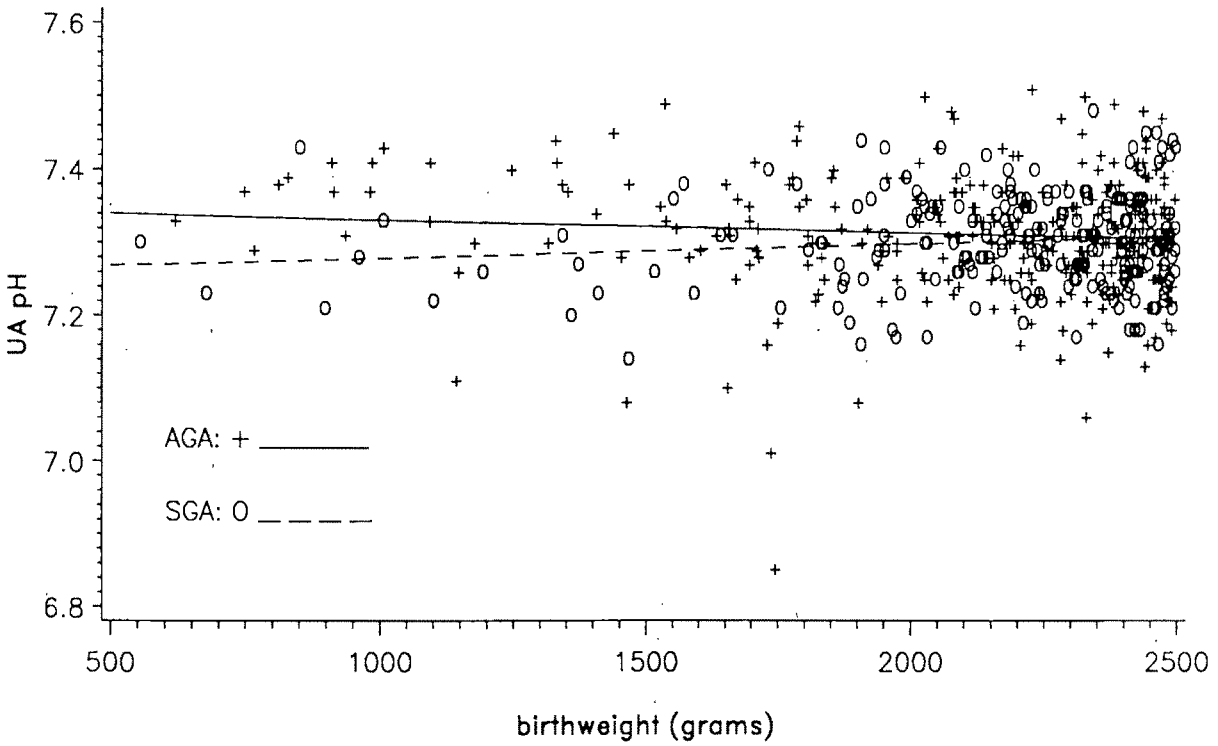

Fig. 4. Scatterplot of umbilical artery pH versus birth weight in 558 newborns. The regression lines for appropriate-for-gestational-age and small-for-gestational age cases are calculated with the following equations: Umbilical artery pH (appropriate-for-gestational-age) = 7.35 − (0.0000171 × birth weight); umbilical artery pH (small-for-gestational-age) = 7.26 + (0.0000204 × birth weight).

Several recent studies have evaluated umbilical artery pH in infants with birth weights ≤2500 gm. Umbilical artery pH was not found to vary with either rising birth weight or lower Apgar scores.[2, 11, 14-16] We also found no change in umbilical artery pH values over the low-birth-weight spectrum (Fig. 4). Sampling of the umbilical artery rather than the umbilical vein appears to be a more sensitive method to assess fetal acid base status because umbilical artery pH values are influenced by umbilical venous pH and fetal metabolism, whereas umbilical venous blood pH values often reflect the presence of either maternal acidosis or alkalosis.[14] Yudkin et al.[14] demonstrated lower umbilical venous pH values but no difference in umbilical artery pH values when low-birth-weight small-for-gestational-age infants were compared with the remaining low-birth-weight population. Although we only sampled the umbilical artery, we found significantly lower pH values in the small-for-gestational-age infants when compared with their appropriate-for-gestational-age counterparts. Our findings are consistent with those of Nickolaides et al.[17] in which acid-base analysis of umbilical artery blood was obtained by cordocentesis in small-for-gestational-age and appropriate-for-gestational-age infants.

We thank the Department of Preventative Medicine and Biometrics at the University of Colorado for statistical analysis of the data and Roger Lenke, MD, for his support.

Preterm delivery: A risk factor for retained placenta

Roberto Romero, MD, Yu Chiung Hsu, MD, Apostolos P. Athanassiadis, MD, Zion Hagay, MD, Cecilia Avila, MD, Jose Nores, MD, Alistair Roberts, MD, Moshe Mazor, MD, and John C. Hobbins, MD

New Haven, Connecticut

The purpose of this study was to determine whether preterm delivery, with and without intraamniotic infection, is a risk factor for retained placenta. This complication occurred more frequently in women with preterm vaginal delivery than in women with term vaginal delivery (9.1% [21/231] vs 1.1% [6/561]; $p < 0.00001$; odds ratio = 9.25). There was no significant difference in the prevalence of retained placenta between women with preterm labor and intact membranes and those with preterm premature rupture of membranes (8% [10/125] vs 10.4% [11/106]; $p \geq 0.05$). A positive amniotic fluid culture or clinical chorioamnionitis was not associated with a higher incidence of retained placenta. This study indicates that preterm delivery is associated with an increased risk of complications of the third stage of labor. (Am J Obstet Gynecol 1990;163:823-5.)

Key words: Placenta, preterm labor, third stage of labor, intraamniotic infection, chorioamnionitis, parturition, retained placenta, prematurity

There is a paucity of information concerning complications of the third stage of labor in women who deliver preterm neonates. During the course of our studies of preterm labor, we made the observation that the incidence of retained placenta was higher in preterm deliveries than in term parturients. Because one of every five preterm neonates is delivered to a woman with a positive amniotic fluid culture for microorganisms,[1] we hypothesized that retained placenta may be associated with microbial invasion of the amniotic cavity. The purpose of this study was to determine whether preterm delivery, with and without intraamniotic infection, is a risk factor for retained placenta.

Material and methods

A retrospective study was undertaken to determine the frequency of retained placenta in women with preterm delivery. Criteria for inclusion into the study were: (1) singleton pregnancy; (2) preterm delivery (20 to 36 weeks); (3) vaginal delivery; and (4) amniocentesis performed on admission for microbiologic studies of the amniotic fluid. The study included patients who delivered in a 25-month period between Jan. 1, 1987, and Feb. 28, 1989, at Yale–New Haven Hospital. Patients were classified into two groups: (1) those with preterm labor and intact membranes and (2) those with preterm

Table II. Prevalence of retained placenta in patients with preterm labor and positive or negative amniotic fluid cultures

	No. of patients	*Patients with retained placenta*	
		No.	*%*
Preterm labor with intact membranes	125	10	8
Positive culture	34	5	14.7
Negative culture	91	5	5.5
Preterm labor with PROM	106	11	10.37
Positive culture	49	6	12.24
Negative culture	57	5	8.8
Control group	561	6	1.1

premature rupture of membranes (PROM). Amniotic fluid was cultured for aerobic and anaerobic bacteria, *Mycoplasma hominis*, and *Ureaplasma urealyticum* as previously described.[2] An intraamniotic infection was defined as the presence of a positive amniotic fluid culture. Clinical chorioamnionitis was diagnosed by the criteria previously described by Gibbs et al.[3] Patients with premature labor, intact membranes, and negative Gram stain examinations of amniotic fluid were treated with tocolytic agents (ritodrine, terbutaline, or magnesium sulfate). Expectant management was undertaken for patients with preterm PROM and a negative Gram stain. Patients with positive Gram stain examinations of amniotic fluid were treated with parenteral antibiotics, and labor was induced.

The standard management of the third stage of labor in our institution is to wait for signs of placental separation before attempting to deliver the placenta. A retained placenta is defined as the lack of spontaneous separation and delivery of the placenta 30 minutes after completion of the second stage of labor. Management of retained placenta consists of manual removal with the patient under general or regional anesthesia. A curettage is performed when there is a suspicion of retained placental fragments.

To determine whether the incidence of retained placenta in preterm gestation was different from that observed after term delivery, a control group consisting of consecutive term vaginal deliveries occurring between Jan. 1, 1989, and Feb. 28, 1989, was studied.

Results

During the study period, there were 231 preterm vaginal deliveries; 125 patients had preterm labor with intact membranes, and 106 had preterm PROM. The control group consisted of 561 patients with vaginal delivery at term.

Table I displays the demographic characteristics of women with preterm labor and intact membranes, women with preterm PROM, and the term control group. No significant differences were detected in any of these parameters among groups. The mean gestational age in the control group was greater than in the study groups.

The incidence of retained placenta was significantly higher in women with preterm vaginal delivery than in women with term vaginal delivery (9.1% [21/231] vs 1.1% [6/561]; $p < 0.00001$; odds ratio = 9.25) There was no significant difference in the incidence of retained placenta between women with preterm labor and intact membranes and those with preterm PROM (8% [10/125] vs 10.4% [11/106]; $p \geq 0.05$).

To determine whether the presence or absence of microbial invasion of the amniotic cavity was a risk factor for retained placenta, analysis was conducted after stratification for amniotic fluid culture results. A positive amniotic fluid culture was not associated with a higher incidence of retained placenta in either of the two groups (preterm labor with intact membranes or preterm PROM) (Table II). Furthermore, a difference in the prevalence of retained placenta between patients with positive and negative amniotic fluid cultures could

not be detected even after patients with preterm labor and intact membranes and patients with preterm PROM were added ($\chi^2 = 1.98$; $p = 0.15$). This study has a power of 80% to detect a difference in proportions between the groups of 10%.

A similar analysis was conducted to establish whether clinical chorioamnionitis was associated with an increased incidence of retained placenta in either group. No statistically significant differences were observed (Table III).

Table III. Prevalence of retained placenta in patients with preterm labor with or without clinical chorioamnionitis

	No. of patients	*Retained placenta*	
		Yes	*No*
Preterm labor with intact membranes			
Clinical chorioamnionitis	5	1	4
Without clinical chorioamnionitis	120	9	111
Preterm labor with PROM			
Clinical chorioamnionitis	15	2	13
Without clinical chorioamnionitis	91	9	82

Comment

The results of this study clearly indicate that the rate of retained placenta is higher in women with preterm vaginal delivery than in women with term vaginal delivery. The incidence of retained placenta in our term control group is consistent with the rate reported in the literature,[4, 5] and therefore our results cannot be attributed to an underestimation of the rate of retained placenta in the control group at term.

Why is preterm delivery associated with a higher incidence of retained placenta? Our first inclination was to attribute this to intrauterine infection. Inflammation at the placental site could lead to abnormalities of the third stage of labor. Our data do not support this hypothesis. However, a limitation of our study is the utilization of amniotic fluid microbiology as an index of intrauterine infection. This method cannot identify intrauterine infections limited to the decidua.

Several alternative explanations may be considered. The currently used definition of retained placenta (failure to deliver after 30 minutes of fetal expulsion) was conceived for the management of the third stage of term labor. There is little information regarding the normal duration of the third stage of preterm labor and delivery. In a recent study examining the duration of placental separation in women undergoing midtrimester prostaglandin E_2 pregnancy terminations, only 37.5% of placentas were delivered spontaneously within 30 minutes.[6] Thus the normal duration of the third stage of labor may be longer in the preterm than in the term gestation. If this is the case, intervention after 30 minutes may be premature and increase the risk for maternal morbidity. An observational study is required to determine the normal duration of the third stage of preterm labor.

The two mechanisms involved in physiologic placental separation are uterine contractions and the formation of a retroplacental clot. As the preterm placenta covers a relatively larger uterine surface than the term placenta, the detachment of a preterm placenta may require more uterine work and time. There are no available data regarding the intensity of uterine contractions during the third stage of preterm labor.

A retained placenta requires manual removal and often a curettage with the patient under anesthesia. These procedures increase the risk for maternal complications, including uterine perforation, hemorrhage, infection, and uterine synechia.[7, 8] In conclusion, preterm delivery increases the risk not only of perinatal mishap but also of maternal complications.

We gratefully acknowledge the assistance of Carol Brekus, MSN, CNM, and Valerie W. Kraemer, MFA.

Fetal umbilical artery Doppler response to graded maternal aerobic exercise and subsequent maternal mean arterial blood pressure: Predictive value for pregnancy-induced hypertension

R. F. Hume, Jr., MD, MAJ, MC, USA,[a] J. D. Bowie, MD,[b] C. McCoy, MD,[a] P. C. Magarelli, MD, PhD,[a] M. Gall, RN,[a] B. S. Hertzberg, MD,[b] B. A. Carroll, MD,[b] and A. P. Killam, MD[a]

Durham, North Carolina

Predictive tests for the identification of women at high risk of the development of preeclampsia are critical to allow the most appropriate preventive measures. Preeclampsia is a vasospastic condition of pregnancy characterized by early and enhanced vascular reactivity to endogenous pressor agents. Exercise tolerance testing with cycle ergometry to induce hemodynamic response measured with duplex Doppler A/B ratio of the umbilical artery could unmask latent vascular pressor hypersensitivity. Our prospective cohort study was designed to test the efficacy of the American College of Obstetricians and Gynecologists exercise in pregnancy guidelines for the low-risk atheletic, physically active, or sedentary patient. The pattern of fetal response to material exercise testing at 28 weeks' gestation was compared with subsequent maternal mean arterial blood pressure and the development of pregnancy-induced hypertension and preeclampsia. Doppler A/B ratio during the recovery period was assessed as below baseline (18) or elevated above resting baseline values (12). Third-trimester blood pressure pattern was assessed to be elevated in 11 patients, 10 of whom had elevated recovery A/B ratios. The Fisher exact test results were ($p = 0.00002$) positive predictive value, 83%; negative predictive value, 94%; sensitivity, 91%; and specificity, 89%. Preeclampsia developed in four patients; all had elevated recovery A/B ratios. Fisher exact test results were ($p = 0.01806$) positive predictive value, 33%; negative predictive value, 100%; sensitivity, 100%; and specificity, 69%. (Am J Obstet Gynecol 1990;163:826-9.)

Key words: Fetal exercise tolerance testing, Doppler velocimetry, preeclampsia

Valid predictive tests for the identification of gravida at high risk of the development of preeclampsia are essential to all efforts of prevention in this critical unresolved area of perinatology. Preeclampsia is a vasospastic condition of pregnancy characterized by early and enhanced vascular reactivity to endogenous pressor agents.[1-5] This heightened vascular tonicity, or reactivity, may be responsible for the early elevations in mean arterial blood pressure (MAP) observed in those gravidae in whom preeclampsia is destined to develop.[6] Doppler flow measurements may offer biophysical assessment of the vascular tone before changes in blood pressure.[7-9] After we have observed the increased immediate recovery phase midumbilical artery A/B ratio response in an obese subject who went on to manifest elevated MAP and subsequently mild preeclampsia (unpublished observation), we formulated the following hypothesis. Exercise tolerance testing (at 60% of the maximum volume of oxygen used) with cycle ergometry to induce hemodynamic response measured with duplex Doppler A/B ratio of the umbilical artery could unmask latent vascular pressor hypersensitivity, and this would be independent of the level of maternal physical fitness.

Material and methods

Volunteers were recruited from our prenatal clinics at Duke University Medical Center. All candidates for the study had a baseline ultrasonographic examination (GE RT 2400) to confirm estimated gestational age, and to exclude cases of multiple gestation, placenta previa, intrauterine growth retardation, and fetal anomalies. Multiparous subjects had no prior history of growth retardation, stillbirth, premature labor, or preeclampsia. Informed consent was obtained in accordance with Duke University Medical Center Institutional Review Board approved protocol. This prospective cohort study design compared the immediate post exertion, or recovery phase, umbilical artery Doppler A/B ratios at 28 weeks' gestation exercise tolerance testing with subsequent maternal MAP and the development of pregnancy-induced hypertension and preeclampsia. Subjects were 30 volunteers from the experimental

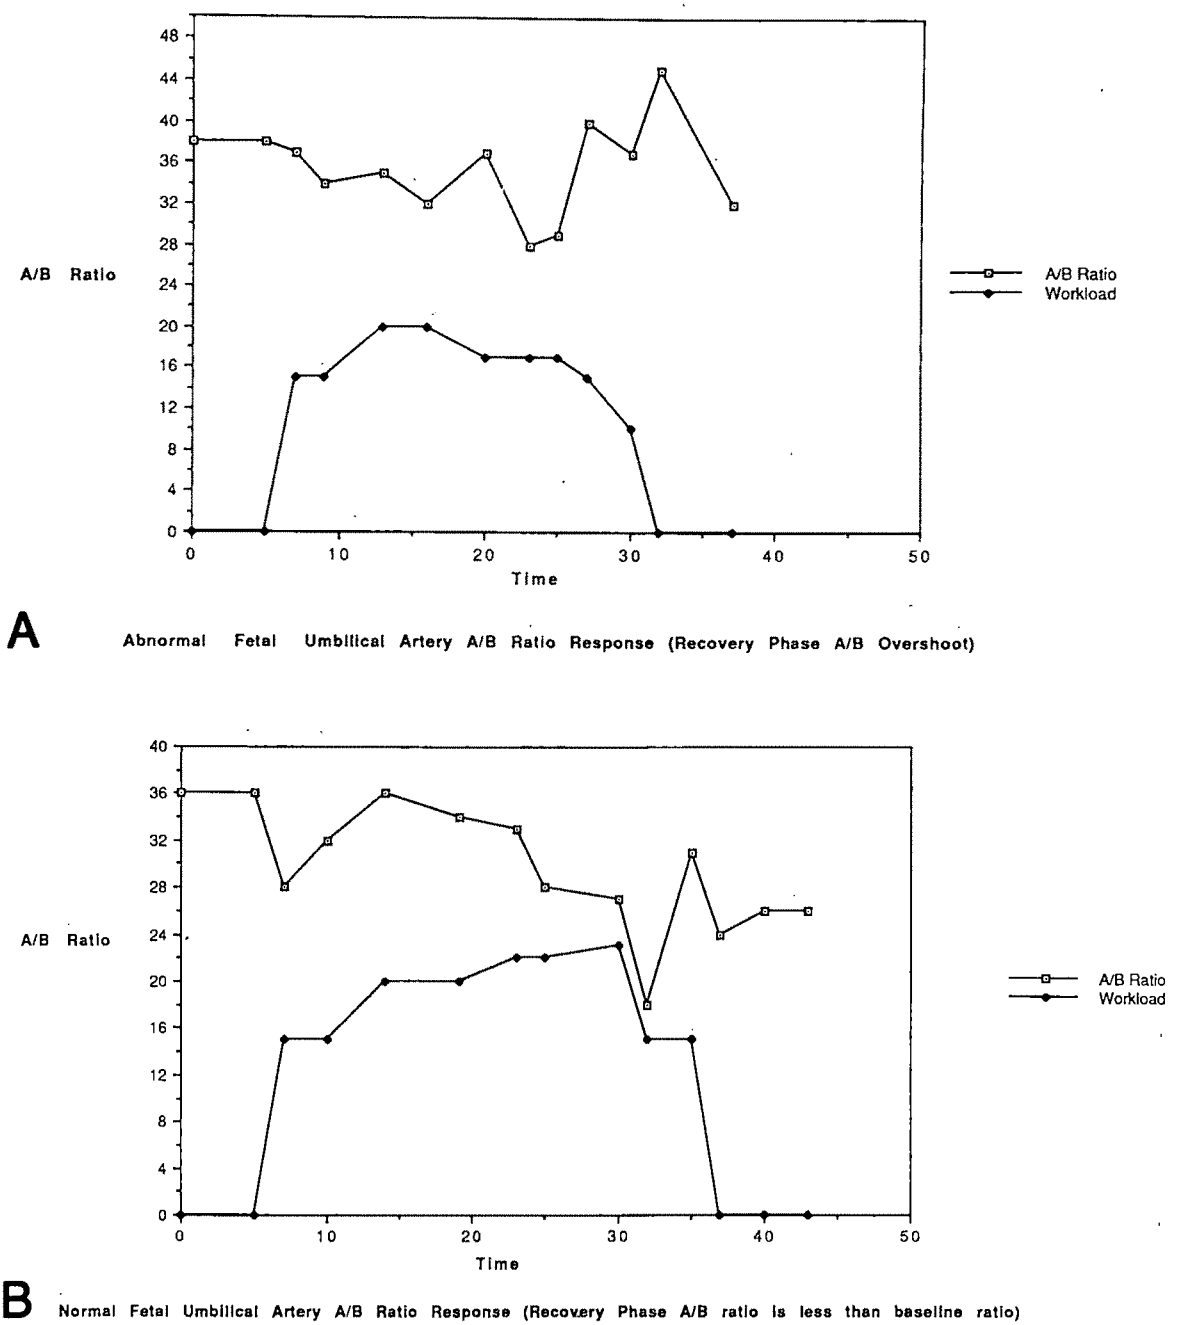

Fig. 1. Fetal midumbilical artery Doppler A/B ratio response to graded maternal aerobic exercise.

study previously presented (Fetal umbilical artery Doppler response to graded maternal aerobic exercise. Presented at the Armed Forces District/American College of Obstetricians and Gynecologists, Denver, Colorado, October 1988, and the Ninth Annual Meeting of the Society of Perinatal Obstetricians, New Orleans, Louisiana, February 2-4, 1989) who were followed-up throughout their pregnancy. Of the 30 subjects, 22 were nulliparous. The distribution of physical fitness category defined by lifestyle and the Canadian Home Fitness Test among the 30 subjects was nine athletes, 16 physically active, and five sedentary.

Exercise tolerance tesing used a FITRON isokenetic cycle ergometer and adhered to American College of Obstetricians and Gynecologists Technical Bulletin guidelines for safe exercise during pregnancy and were generally in the mild-moderate aerobic range (60% of the maximum volume of oxygen used). Ultrasonographic surveillance (Acuson 128, Acuson, Mountain View, Calif.) was continuous throughout standard aerobic exercise and included observation of fetal heart rate, breathing, movement, and pulsed duplex Doppler A/B ratio of the midumbilical cord artery measured serially during all exercise phases in the

Specificity (%)	89	69
Positive predictive value (%)	83	33
Negative predictive value (%)	94	100

seated position; 5-minute baseline, 5-minute warm-up, 15- to 20-minute sustained, 5-minute cool-down, and 5- to 10-minute recovery. Maternal heart and respiratory rate response to exercise determined the exact time and duration of each phase to achieve 15 minutes at 140 beats/min recommended by the American College of Obstetricians and Gynecologists. Serial ultrasonographic evaluations for growth, amniotic fluid volume, and fetal well-being were performed monthly until delivery.

The normal exercise tolerance testing umbilical artery Doppler A/B ratio response is to decrease during and after exertion(Fig. 1, *A*). This suggests less resistance to flow, less impedance, and normal vascular reactivity. Abnormal exercise tolerance testing umbilical artery Doppler A/B ratio response is to increase above the resting baseline, suggesting greater vascular reactivity in response to exertion (Fig. 1, *B*). The immediate post exertion recovery phase A/B ratios were determined to be normal or elevated above the resting baseline A/B ratio values, each subject serving as her own control. The values obtained at the 28-week exercise tolerance testing were compared with subsequent maternal MAP values.

(MAP = [Systolic blood pressure + (2 × Diastolic blood pressure)] / 3) is defined as abnormal if >105 mm or if increased >20 mm compared with first-trimester baseline values (American College of Obstetricians and Gynecologists Committee on Terminology). The obstetric records were reviewed by an observer blinded to exercise tolerance testing umbilical artery Doppler A/B response to obtain diagnoses of pregnancy-induced hypertension, preeclampsia, and delivery outcome. All subjects registered for prenatal care in the first trimester. The initial clinic MAP (first three visits) and the late third-trimester MAP (last three visits) were calculated and used in the comparison.

Nonparametric statistical methods were used, (χ^2 or the Fisher extact test), and predictive values, sensitivity, and specificity of exercise tolerance testing umbilical artery Doppler A/B as a screening test were determined.

Results

No maternal injuries or fetal bradycardia, distress, or tachypnea occurred during the exercise tolerance testing. All subjects' resting baseline Doppler A/B ratios were normal for gestational age. Each subject served as her own control for the definition of abnormal response, recovery overshoot. Doppler A/B ratio during the recovery phase was assessed to be below resting baseline in 18 of 30 subjects and elevated above resting baseline in 12 of 30 subjects. Third-trimester maternal blood pressure was assessed to be elevated in 11 subjects, 10 of whom had elevated recovery A/B ratio response to exertion. Preeclampsia developed in four subjects; all had elevated recovery A/B ratios.

Table I presents the data in summarized form according to maternal fitness and parity. All cases of preeclampsia occurred in nulliparous subjects. The elevated exercise tolerance testing umbilical artery Doppler A/B response and increased MAP and preeclampsia occurred in all fitness categories. Physical fitness may be unrelated to vascular pressor sensitivity. The statistical analyses of the association of exercise tolerance testing umbilical artery Doppler A/B ratio recovery overshoot to maternal MAP (Fisher exact test, p = 0.00002) and pregnancy-induced hypertension

and preeclampsia (Fisher exact test, $p = 0.01806$) are presented in Tables II and III, respectively. The predictive value of the exercise tolerance testing umbilical artery Doppler A/B ratio unmasking subsequent increased MAP is positive predictive value 83%, negative predictive value 94%, sensitivity 91%, and specificity 89%. The predictive value of the exercise tolerance testing umbilical artery Doppler A/B ratio for preeclampsia is positive predictive value 33%, negative predictive value 100%, sensitivity 100%, and specificity 69%.

Comment

The statistical analyses of the association of altered umbilical artery A/B ratio response to maternal exertion and MAP reflect the pathophysiology of preeclampsia and the physiologic response to exercise in the gravid woman. Exercise is known to induce the release of endogenous vasopressor agents such as norepinephrine, epinephrine and atrial natriuretic factor.[10] The recovery phase of aerobic exercise is particularly a period of enhanced hyperdynamic response to the oxygen debt and the lactic acid load released from the working muscles and the increased catecholamine levels.[10, 11] The response of atrial natriuretic factor, vasopressin, and angiotensin II in the gravid are less clear in human research. Regardless of the specific agent(s) responsible it is clear that there is a generalized increase in endogenous vasoactive activity during and immediately after exercise.

Preecalmpsia is associated with alteration in placental, decidual, and umbilical artery prostanoid metabolism favoring vasospasm—prostacyclin versus thromboxane imbalance.[12, 13] This thesis seems to be strongly supported by the success of aspirin therapy in the prevention of preeclampsia in a cohort of angiotension II hypersensitive gravidae.[14] The final pathway of the pathophysiology of preeclampsia would seem to be related to the endothelial hypersensitivity to the endogenous vasopressors (renin, angiotensin II, artrial natriuretic factor)[15-18] because of this altered prostanoid metabolism.[19] This alteration of vascular reactivity is measurable with existing Doppler ultrasonographic technology.[20] The latent hypersensitivity that we measure during the immediate recovery phase could be unmasked through the induction of endogenous vasoactive agents in response to maternal exertion. Fetal exercise tolerance testing (exercise tolerance testing umbilical artery Doppler) may serve as a practical predictive test for such vascular hypersensitivity. Larger numbers of study patients are necessary to determine the clinical usefulness of this diagnostic tool.

The Shirodkar operation: A reappraisal

Faith J. Frieden, MD, Steven A. Ordorica, MD, Iffath A. Hoskins, MD, and Bruce K. Young, MD

New York, New York

Sixty-six cerclages were performed by one surgeon in 46 patients with documented cervical incompetence. The mean operative blood loss was 25 ml, and the mean operating time was 18 minutes with no postoperative morbidity. Fifty-five of the pregnancies were carried for at least 37 weeks, eight were delivered before 37 weeks, and three are continuing. Six of the eight preterm deliveries were a result of factors unrelated to cervical incompetence. The two remaining preterm births were probably also unrelated because one occurred 8 days after emergent cerclage placement and the other occurred 12 weeks after the procedure, both as a result of premature rupture of membranes. There were no cesarean deliveries related to the Shirodkar suture. The efficacy of the procedure was demonstrated by a corrected perinatal survival rate of 100% and term delivery of 88%. (Since this article was written all three of the undelivered patients were delivered of infants after 37 weeks' gestation for a term delivery rate of 88% with 100% neonatal survival.) (Am J Obstet Gynecol 1990;163:830-3.)

Key words: Shirodkar procedure, cervical cerclage, incompetent cervix

Operative correction of the incompetent cervix has been debated since the 1950s when Lash and Lash,[1] Shirodkar,[2] and McDonald[3] described their techniques. The two most commonly used operations are the Shirodkar and McDonald cerclages. However, the Shirodkar procedure is particularly useful in cases with old lacerations or gross anatomic defects of the cervix and therefore is the most universally applicable. Currently there is a lack of exposure to the Shirodkar operation in obstetric training because it is not frequently performed. This retrospective study summarizes one author's (B. K. Y.) experience with the Shirodkar operation and suggests further consideration of this procedure.

Material and methods

During the period between 1974 and 1989 46 patients underwent 66 Shirodkar procedures. All patients had a history of midtrimester fetal loss with painless cervical dilatation. All patients except one had a workup between pregnancies demonstrating at least one objective test (hysterosalpingogram, hysteroscopy, or passage of a no. 8 Hegar dilator), thus confirming the diagnosis of incompetent cervix. There was visible cervical dilatation with bulging membranes in patients who had emergency cerclage, including the one patient with a positive history but no diagnostic work-up.

The operation was performed electively between 13 and 18 weeks' gestation and emergently as late as 24 weeks. The procedure was done with the patient under regional anesthesia; only two patients required general anesthesia for failed epidural.

The cerclage was performed after the method described by Shirodkar[2] with slight modification as follows. The anterior and posterior lips of the cervix are grasped with sponge forceps. A 1 cm transverse incision is made with scissors anteriorly, at the cervicovesical junction, and the bladder is advanced cephalad, past the level of the internal os, using blunt dissection (Fig. 1). A similar incision is made posteriorly and the peritoneum is bluntly reflected past the level of the internal os (Fig. 2) off the cervix. Instead of a strip of fascia lata from the patient's thigh, as described by Shirodkar, a 5 mm Mersilene band doubly armed with curved needles is placed submucosally from posterior to anterior on each side of the cervix at the level of the internal os and is tied anteriorly (Fig. 3). No anchoring sutures are used and the internal os is closed to <1 cm diameter by tying the Mersilene band. The vaginal mucosa is closed at both incisions with a running locked 00-chromic suture, burying the Mersilene band and achieving hemostasis. No packs or drains are used and no catheterization is necessary.

Postoperatively the patients are maintained on bed rest with bathroom privileges and prophylactic tocolytics are given for 12 to 24 hours. Thereafter their activity is limited only by the usual pregnancy restrictions. The suture is removed with the patient under

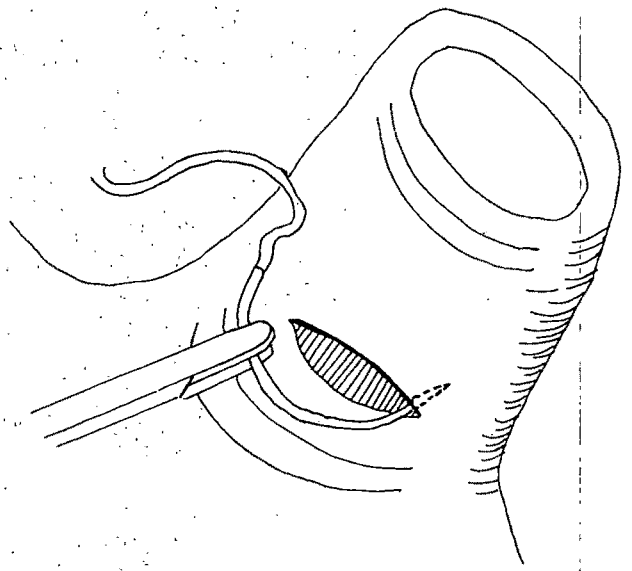

Fig. 2. Posterior incision and needle being passed.

epidural anesthesia at the onset of labor by incising the mucosa over the knot and cutting the Mersilene band. The mucosa is not sutured unless there is significant bleeding, which rarely occurs.

Results

In this series 46 patients underwent 66 Shirodkar procedures. Only one procedure was performed during a given pregnancy (none required repetition), but some patients were treated for more than one pregnancy. The average gestational age at the time of the cerclage was 15.3 weeks. Mean estimated blood loss was 25 ml (range, 10 to 50 ml), and mean operative time was 18 minutes (range, 12 to 35 minutes).

Before their first cerclage procedure in this study the patients had a total of 94 pregnancies beyond the first trimester with a fetal survival rate of 35%. In our series 55 of the 66 treated pregnancies were carried to 37 weeks or more. Eight patients were delivered before 37 weeks and three women had continuing pregnancies with gestational age >32 weeks at the time of this report (Fig. 4). The preterm births consisted of one at 30 weeks with abruptio placentae, one at 34 weeks because of hemorrhage secondary to placenta previa, one at 34 weeks by cesarean section for severe preeclampsia, three intrauterine fetal deaths between 16 and 32 weeks, and two with spontaneous amniorrhexis at 17 and 26 weeks. Thus only the last two of these preterm deliveries might be attributed to cervical incompetence. However, it is unlikely that even these losses were related to cervical incompetence because one occurred 8 days after emergent correction at 3 cm dilatation and necessitated use of prostaglandin E_2 suppositories to empty the uterus, and the other occurred 12 weeks after the cerclage with ruptured membranes and labor. Consequently the corrected outcome, excluding fetal death and preterm deliveries unrelated to cervical incompetence, was 100% of patients delivered at or beyond 37 weeks' gestation.

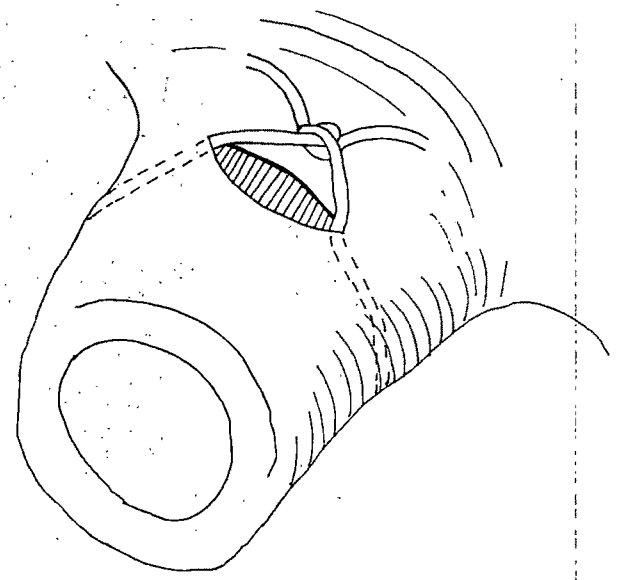

Fig. 3. Knot tied anteriorly.

A group of nine patients had previously undergone 14 unsuccessful cerclage procedures elsewhere (Table I). These same patients were treated subsequently by the authors in 16 pregnancies, and all were carried to 37 weeks or longer with 100% neonatal survival.

There were some patients who had more than one Shirodkar operation, with a maximum of five procedures in one patient. Multiple procedures did not pre-

clude vaginal birth. No cesarean deliveries were performed for indications related to the Shirodkar operation, and an attempt at vaginal delivery was made in every case unless contraindicated for obstetric reasons. The primary cesarean section rate in our series was 23%. In half of the cases a cesarean section was performed for cephalopelvic disproportion. Other indications for primary cesarean section were history of previous extensive cervical laceration with hemorrhage, double footling breech presentation, retinal detachment, severe preeclampsia, prior uterine rupture, and hemorrhage caused by placenta previa. There were no cases of bladder, ureteral, or bowel injury, hemorrhage, or infection. There were no postoperative preterm labors in the first 7 days after the procedure. No patients had uterine rupture or significant cervical laceration by awaiting the onset of labor before removal of the Mersilene band. Three patients did require repair of minor cervical lacerations at suture removal but did not require transfusion since bleeding was minimal. Laceration repair was necessary in two patients in three pregnancies because of a delay in suture removal with precipitate labor and in one patient as a result of a forceps delivery. In two other patients difficulty was encountered in removing the suture but the remaining patients' sutures were easily removed. No patients had infertility or bladder disorders, fistula formation, granuloma formation, or dysmenorrhea after the placement and subsequent removal of the Mersilene band. No long-term adverse effects were noted.

Comment

The pathophysiology of cervical incompetence is not clearly defined. It is probably not one specific abnormality but rather a spectrum of different degrees of anatomic deficiency, including congenital connective tissue defects, multiple small lacerations as a result of trauma, gross cervical tears, and congenital malformations, such as those seen in patients with diethystilbestrol exposure. Varying patterns of uterine contractions as a result of the effects of physical activity and multiple gestation further contribute to cervical incompetence. The final common pathway for cervical incompetence as a result of these factors is painless dilatation of the cervix.

As in all areas of medicine, a correct diagnosis is essential to obtain the optimal therapeutic result. Therefore prepregnancy evaluation and appropriate selection of patients for operation are paramount. Scheduled prophylactic operation in the early second trimester offers a further safeguard because cervical dilatation usually has not yet taken place and the membranes are not exposed. This not only protects the gestational sac, but also simplifies the operative procedure and reduces blood loss. The early second trimester is also preferred because early spontaneous abortion for other causes is no longer a problem. Ultrasonographic verification of fetal viability should be done before the operation is performed.

A recent review of cervical incompetence by Golan

et al.[4] cites fetal survival rates after Shirodkar cerclage of 75% to 85%. In our series 58 of the 66 treated pregnancies (88%) were carried for at least 37 weeks, with 61 surviving infants for an uncorrected perinatal survival rate of 92%.

This is the largest published series of patients treated for incompetent cervix with the Shirodkar operation by a single surgeon. It demonstrates that the operation is effective when used for patients with documented cervical incompetence. There was no morbidity from the procedure, and removal of the Mersilene band as soon as labor began permitted vaginal birth without significantly increased risk to the mother or infant. The Shirodkar operation should be part of resident training and should have a prominent place in the treatment of incompetent cervix. Perhaps a prospective randomized trial that compares the Shirodkar and McDonald procedures should be undertaken to determine the relative merits of these techniques.

We thank Dennis S. Chi and Sara Truesdell for their assistance in preparation of the manuscript.

The effect of mode of delivery on the perinatal outcome in fetuses with abdominal wall defects

Michael Moretti, MD, Aldo Khoury, MD, Jaime Rodriquez, MD, Thom Lobe, MD, David Shaver, MD, and Baha Sibai, MD

Memphis, Tennessee

A descriptive study of 125 infants with abdominal wall defects was undertaken to determine the effect of mode of delivery on outcome. Fifty-six infants had gastroschisis and 69 had omphalocele. Overall, there were no differences between the omphalocele and the gastroschisis groups in either cesarean section rate (22% vs 26%) or prematurity rate (26% vs 30%). However, the omphalocele group had a significantly higher infant death rate (22% vs 7%, $p < 0.001$), a significantly higher incidence of associated major congenital anomalies (29% vs 5%, $p < 0.001$), and a higher incidence of long-term infant morbidity (14.5% vs 8.9%). Within either group there was no significant difference between vaginal and cesarean delivery regarding either infant mortality, acute or long-term infant outcome, or frequency of associated major anomalies. We conclude that vaginal delivery of infants with abdominal wall defects does not adversely affect infant outcome. (AM J OBSTET GYNECOL 1990;163:833-8.)

Key words: Congenital abdominal wall defects, vaginal delivery, outcome

The incidence of omphalocele is approximately one in 5,800 to one in 5,130 live births, while that of gastroschisis is about one in 10,000 to one in 15,000 live births.[1] Omphalocele represents the persistence of the body stalk in an area normally occupied by the differentiated abdominal wall. A membranous sac usually covers the herniated viscera. Omphalocele is associated with major chromosomal abnormalities. This is reported to be as high as 40% of patients where amniocentesis is performed. In addition, there is an increased incidence of other major structural abnormalities (45%) Gastroschisis involves a defect in the abdominal wall usually to the right of the umbilicus. It has been suggested that this results from abnormal involution of the right umbilical vein that leads to a paraumbilical defect through which small bowel prolapses at approximately 37 days of embryonic life. In gastroschisis, viscera float

uncovered in the amniotic fluid and lie exposed at birth. The incidence of major chromosomal abnormalities or other structural anomalies is low in this group of fetuses (<5%). Prematurity and low birth weight have been reported to be more common than in omphalocele.[2-4]

There has been an increase in the survival of infants with these defects over the past 10 years. Mortality is related to a number of factors: gestational age at the time of delivery, the condition of the infant before operation, the presence of other anomalies, the size of the lesion, and the type of repair.[5] Now, with the widespread use of obstetric ultrasonography, congenital defects of this sort are being detected in utero with increasing frequency.[6] Since prenatal diagnosis offers the ability to alter the obstetric management, it is important to focus attention on other perinatal factors that may influence neonatal and long-term outcome. Debate has arisen as to the appropriate mode of delivery. Early case reports advocated the use of cesarean section to avoid fetal injury.[7-9] Lenke et al.[10] recommended the use of cesarean section in fetuses with gastroschisis while Nakayama et al.[11] and Kirk and Wah[5] reported that vaginal delivery did not appear to adversely affect fetal outcome for these fetus. In addition, Carpenter et al.[12] reported that vaginal delivery is not contraindicated for the fetus with ventral wall defects.

The purpose of this report is to review our experience of 125 cases of anterior abdominal wall defects and to determine the effect of mode of delivery on neonatal survival and long-term outcome.

Material and methods

The study group consisted of infants with omphalocele or gastroschisis who were referred to the neonatal surgical team at the University of Tennessee, Memphis, between August 1978 and July 1989. Data were collected by chart review performed by the authors. The source of the data included office records of the pediatric surgical team, inpatient and outpatient records of the hospital of origin, records from the neonatal intensive care unit, and, when applicable, autopsy reports. Details of long-term follow-up were obtained from the pediatric clinic that the patients attended and by direct contact with the parents of the infants.

Records were reviewed for birth weight, gestational age, mode of delivery, presence of other major anomalies, size of the defect, and presence of extracorporeal organs, as well as the presence of other neonatal complications. Special attention was given to the ascertainment of trauma to the extracorporeal organs at delivery and, in the case of omphalocele, rupture of the sac. In those cases of omphalocele with a ruptured sac records were carefully reviewed to determine those that appeared to occur at delivery. This was determined principally by observations of the bowel serosa and the presence of thickened matted bowel. It was thought that those infants who had these associated bowel findings most likely sustained rupture of the omphalocele sac before delivery. The changes in the bowel serosa were attributed to exposure of the bowel to the alkaline amniotic fluid, similar to that of gastroschisis.

Gestational age at birth was estimated from the mother's last menstrual period and confirmed where possible by a dating ultrasonogram and Dubowitz examination. Definition of the extent of the ventral wall defect and evidence of any trauma were based on records of the examination by the pediatric surgical team on admission to their unit. The criteria defined by the pediatric surgical team for the diagnosis of omphalocele included those patients with a midline abdominal wall defect with a covering membrane or a remnant of the membrane. Additional criteria included the presence of a dilated umbilical ring containing umbilical vessels passing through the membranous sac without an intervening bridge. The criteria for the diagnosis of gastroschisis were a paraumbilical full-thickness defect of the abdominal wall and a normal umbilical cord insertion independent of the defect with a skin bridge between the ventral defect and the umbilical ring.

The analysis was focused on perinatal outcome, long-term outcome, incidence of surgical complications, and cause of death. The infants were divided into four groups according to mode of delivery for analysis: gastroschisis vaginal group versus gastroschisis cesarean section group and omphalocele vaginal group versus omphalocele cesarean section group.

Analysis of data was performed with χ^2 or Fisher's exact test when appropriate and by Student's t test. A p value of <0.05 was considered significant.

Results

A total of 125 infants was studied: gastroschisis ($n = 56$) and omphalocele $n = 69$). Thirty patients (23.5%) were delivered by cesarean section (21% in omphalocele group and 26% in gastroschisis group). The indications for cesarean section are listed in Table I. One hundred four infants (83%) were delivered at this center. Prenatal diagnosis of the defects was made in 10 (8%) of the cases. All of the infants with ventral wall defects that were diagnosed prenatally were delivered at this center [gastroschisis ($n = 4$) omphalocele ($n = 6$)]. All of the infants with gastroschisis that was diagnosed prenatally survived. Five of six infants with prenatal diagnosis of omphalocele survived. The prematurity rates overall were 26% and 30%, respectively.

Table II summarizes the neonatal and long-term outcome of infants with gastroschisis according to the mode of delivery. There were no significant differences between the vaginal and cesarean section groups re-

garding any of the categories studied. The overall mortality rate in infants with gastroschisis who were delivered by cesarean section was 6.6% and it was 7.3% in the infants who were delivered vaginally. In the gastroschisis group overall, the delivery-operation interval was an average of 6 hours. There was little difference in this interval between the cesarean section group (6.0 hours) and the vaginal delivery group (6.2 hours).

Gastroschisis–vaginal delivery group: Extracorporeal organs other than bowel were present in 16 (28%) of these infants. These included stomach, bladder, fallopian tubes, ovary, omentum, and testis. Extracorporeal liver was not found in any infant within this group. There were no cases of delivery trauma to the extracorporeal organs noted. Intestinal atresia was present in three infants. Overall, 21 infants in this group had primary closure of the defect and 20 required a two-stage repair. Additional bowel surgery was necessary in four infants: bowel resection for volvulus or obstruction ($n=3$), and ileostomy closure $n=1$). It is interesting to note that meconium aspiration syndrome did not occur in any of these neonates. There were three (7.3%) infant deaths in this group: one caused by fungal sepsis at 17 days, one caused by sudden infant death syndrome at 6 weeks, and a late death that was secondary to bowel obstruction and sepsis at 3 years. Long-term follow-up was available for all 41 infants. Three infants suffered from significant morbidity: One infant had long-term nutritional problems and was on a modified diet as a result of short bowel syndrome, one infant had biliary cirrhosis, and the third had failure to thrive.

Gastroschisis–cesarean delivery group. Associated major anomalies were present in two (13%) of these infants: One infant had occipital encephalocele and one infant had trisomy 13 and a large ventricular septal defect. This latter case represented the only infant death among cases of gastroschisis with delivery by cesarean section. Extracorporeal organs present in this group of infants included bladder, stomach, gallbladder, ovaries, and fallopian tubes. None had an extracorporeal liver. Delivery trauma to the extracorporeal organs was not noted in any infant. Associated intestinal atresia was noted in two infants in this group. Primary closure was performed in eight and seven infants required a two-stage repair. Additional bowel surgery (closure of jejunostomy) was necessary in only two infants. All 15 infants had long-term follow-up, and none had any long-term morbidity.

Table III summarizes the clinical characteristics of infants with omphalocele according to the mode of delivery. There were no significant differences for any of the categories studied. The overall mortality rate in infants with omphalocele was 20% in those delivered by cesarean section and 22% in infants delivered vaginally. The causes of infant deaths in the omphalocele group include multiple congenital anomalies ($n=9$), cardiac anomalies ($n=4$), and complications of prematurity ($n=2$).

Table I. Indications for cesarean section

	Omphalocele (n = 15, 22%)	*Gastroschisis (n = 15, 26%)*
Failure to progress–cephalopelvic disproportion	4	3
Elective repeat	4	2
Fetal distress	3	6
Breech	2	2
Other	2*	2†

*Premature rupture of membranes and chorioamnionitis ($n = 1$), maternal genital herpes ($n = 1$).
†Preeclampsia ($n = 2$).

In the omphalocele group the delivery-operation interval was an average of 6.5 hours. There was little difference in the interval between the cesarean section group (6.6 hours) and the vaginal delivery group (5.8 hours).

Omphalocele–vaginal delivery group. There were 16 (30%) infants with major associated anomalies and 22 (41%) with extracorporeal organs other than bowel present. These included stomach, pancreas, spleen, ovary, and fallopian tubes. Eleven infants had extracorporeal liver (partial or complete). There were three (27%) infant deaths among the babies with herniated liver delivered vaginally. Severe cardiac anomalies were the cause of death in two of these infants (Epstein's anomaly, transposition of the great vessels). The third infant died of complications of prematurity. Delivery trauma to the liver was not noted in any of the 11 cases. Eight infants with omphalocele who were delivered vaginally had ruptured sacs. On the basis of examination of the bowel, it was determined that two of the eight must have sustained rupture of the sac before delivery. Among the eight infants with ruptured sacs, there were two infant deaths, both of which were attributed to multiple congenital anomalies. There were no cases of sepsis among these eight infants. Among the infants with omphalocele delivered by the vaginal route, there were three infants with associated intestinal atresia. Thirty-four infants had primary repair and 20 required a two-stage operation. Overall, among the cases with omphalocele and vaginal delivery there were 12 infant deaths, 10 of which were associated with major anomalies and two that were secondary to complications of prematurity. There were 36 surviving babies with isolated omphalocele that underwent vaginal delivery. Thirty-five survived without long-term morbidity, and one died with complications of bowel obstruction at 2 years. Long-term follow-up was available for

all the infants in the omphalocele–vaginal delivery group. Six infants had significant morbidity: Two had other congenital anomalies (severe scoliosis, ureteral pelvic obstruction), two suffered from complications of preterm birth (chronic respiratory problems), one infant had recurrent urinary tract infections, and the last infant had short bowel syndrome and cirrhosis. This infant had associated intestinal atresia.

Omphalocele–cesarean section group. There were four (27%) infants with major congenital anomalies. Six infants had extracorporeal organs other than bowel. These included stomach, spleen, and bladder. There were five cases with extracorporeal liver. Of these five infants, four survived and were without long-term morbidity. The fifth infant had pentalogy of Cantrell. This infant died after operation. One infant in the omphalocele–cesarean section group had a ruptured sac at delivery. This was reported specifically to have occurred at the time of delivery. The status of the bowel did not indicate prior rupture. This infant survived without long-term morbidity. One infant had an associated intestinal atresia. Primary closure was performed in eight patients in this group and a two-stage repair was necessary in seven. Overall, there were three infant deaths in this group (20%). Two were due to major cardiac anomalies and the third was attributed to extreme prematurity and respiratory complications. Long-term follow-up was available for all 15 patients. Three infants (20%) had long-term complications, all of which were attributed to associated congenital anomalies: atrial septal defect and obstructed ureteropelvic junction, inperforate anus and absent sacrum, and meningomylocele.

Comment

The overall survival rate of 80% in this study is consistent with that reported in other recent studies.[5] The higher mortality rate with omphalocele is also consistent with that of other reports.[3, 12] This increased mortality in the omphalocele group is attributed to the higher rate of associated major anomalies in the omphalocele group as opposed to those infants with gastroschisis (29% vs 5.0%). There was an increased trend toward low birth weight and preterm delivery in the infants with gastroschisis as opposed to those with omphalocele, but the difference did not reach significance. In no case was cesarean section performed solely because of the prenatal diagnosis of abdominal wall defect. This study did not focus on the prenatal diagnosis of these anomalies. Prenatal diagnosis of the defect was made in only 8% of the cases. Although there was no difference in survival between those infants in whom

the defect was diagnosed prenatally and those with diagnosis at delivery, it has been shown in other reports that prenatal diagnosis improves management by allowing maternal transport for labor and delivery at a center specializing in high-risk pregnancy and pediatric intensive care. A key factor in postnatal survival is the clinical condition of the newborn on admission to the pediatric surgical team. Delays in neonatal transport after birth can increase the chances of profound dehydration and risk of sepsis, both causes of poor outcome.[11] In addition, prenatal assessment can determine other associated lethal anomalies and prevent some cesarean deliveries. All the infants were cared for by the same neonatal surgical team. Thus treatment was consistent in all cases.

The most commonly reported postoperative complications in infants with gastroschisis are sepsis, small bowel obstruction, and infarction.[3] It is hypothesized that the combination of uterine contractions and vaginal delivery may lead to vascular compromise and compression of the bowel, thus increasing the chances for these complications. This theory could explain the need for more secondary operations and the greater postoperative complication rate in infants born via the vaginal route.[10] In this study three infants with gastroschisis delivered vaginally required secondary operation for bowel obstruction, but two of the three had associated bowel atresia and required more involved initial surgery. Thus these complications are not due to the delivery process itself but rather are caused by the prenatal state of the organs, such as the presence of secondary bowel atresia. In one other infant massive fungal sepsis resulted in neonatal death at 17 days of age. This infant had an associated major anomaly (bladder extrophy), and sepsis developed late in the postoperative period. Thus it is unlikely that such a complication was associated with the delivery process.

Since one of the major issues in selecting the mode of delivery in these infants is the risk of delivery trauma to the extracorporeal organs, it is important to note that in the 41 infants with gastroschisis delivered vaginally no cases of trauma to the extracorporeal organs at delivery were reported. None of the infants in the gastroschisis group had extracorporeal liver. Thus the effect of mode of delivery in this particular situation cannot be addressed in this study.

Ten of the 12 infant deaths in the omphalocele–vaginal delivery group were due to associated major congenital anomalies and two were due to severe hyaline membrane disease. It is of interest that there were eight cases of ruptured sac in the omphalocele–vaginal delivery group, none of which were complicated by sepsis. Although extracorporeal liver was a relatively common finding in the omphalocele group (22%), there was no improvement in survival rate when the infant was delivered by cesarean section rather than vaginally. This is in contrast to the findings of Sermer et al.,[3] who reported a neonatal death rate of 88% in infants with omphalocele and herniated liver. However, in that report no mention was made as to the presence of other congenital anomalies or perinatal complications that may have contributed to the poor outcome in that group of infants.

There were 36 infants with isolated omphalocele delivered by the vaginal route. There was only one infant death in this group, the cause of which could not have been delivery mode. This further emphasizes the safety of vaginal delivery in this group of patients. In addition, the data support the fact that the majority of the mortality and morbidity in patients with omphalocele can be attributed to other complicating factors, mainly associated congenital anomalies and chromosomal aberrations. Since the primary admission criterion for this study was referral to the pediatric surgical team, it may be postulated that a number of infants were not referred for care because their conditions were critical and that this could be due to visceral trauma sustained at delivery. We feel that this is unlikely for a number of reasons. All infants in this region requiring neonatal intensive care are transferred to this medical center. It is unlikely that visceral trauma would preclude transfer. Facilities for transfer are available, despite the critical nature of the condition of the infants. All infants that present to the neonatal intensive care unit with this sort of lesion would have a pediatric surgical consultation despite their critical condition. Review of the records of the pediatric surgical team would suggest that few cases have been overlooked. We did not focus our analysis on the incidence of stillbirths among fetuses with ventral wall defects nor did we examine the effect of mode of delivery on survival of the previable infant (<24 weeks) with ventral wall defects. We feel there are too many confounding variables to adequately compare these groups.

In summary, our findings suggest that vaginal delivery of infants with abdominal wall defects does not have an adverse effect on neonatal outcome. In addition, long-term infant outcome does not appear to be affected by mode of delivery but rather by other perinatal events. Moreover, the presence of extracorporeal liver in fetuses with omphalocele does not necessarily preclude a vaginal delivery. Until a large, multicenter, prospective randomized study can be accomplished, we believe that cesarean section should be reserved only for obstetric indications in fetuses with abdominal wall defects.

Perinatal survival with expectant management of midtrimester rupture of membranes

Carol A. Major, MD, and John L. Kitzmiller, MD
San Francisco, California

A retrospective study of 70 patients with preterm premature rupture of membranes before 26 weeks of gestation was performed. The purpose of this study was to examine the perinatal outcome and the potential maternal and neonatal morbidity associated with this obstetric condition. The mean gestational age at diagnosis of rupture of membranes was 23.7 weeks. The latency period ranged from 24 hours to 60 days with the mean being 12 days. There was no correlation between gestational age at rupture of membranes and latency period. Seventy-one infants were delivered. The perinatal survival was 63%. Sixty-eight percent of the survivors had normal neurological and physical development at a 1-year follow-up. Amnionitis developed in 43% of patients. The incidence of respiratory distress syndrome in the neonates was 52%. Betamethasone did not appear to reduce this incidence. The perinatal survival in patients with midtrimester rupture of membranes appears to be improving with the advancements in neonatal care of the extremely premature infant. (AM J OBSTET GYNECOL 1990;163:838-44.)

Key words: Premature rupture of membranes, expectant management, midtrimester, amnionitis, perinatal survival

Premature rupture of membranes (PROM) before the onset of labor occurs in approximately 10% of all pregnancies.[1] The incidence of preterm PROM is about 1%.[2,3] Despite the large amount of data generated concerning the topic of preterm PROM, it remains one of the most controversial topics in obstetrics today.[4] The management of patients with very early preterm PROM in past years usually involved termination of the pregnancy in an attempt to prevent potential maternal morbidity and mortality. In these cases the thought was that the maternal risks greatly outweighed the chances for a normal neonatal outcome. With recent improvements in the neonatal care of the extremely premature infant, there has been an increased interest in the practice of expectant management of patients with preterm PROM.[5]

There have only been four published reports examining the maternal and neonatal outcomes of patients with midtrimester PROM.[6-9] The perinatal survival ranged from 24% in the study by Taylor and Garite[6] in 1984 to 51% in the study by Bengtson and VanMarter[9] in 1988. From these studies and ours, it

appears that the perinatal survival rates in midtrimester PROM have steadily improved as neonatal care for very-low-birth-weight infants has continued to develop. The contributions of obstetric procedures and regimens are less certain.

In our study, we examined the maternal morbidity of 70 patients with preterm PROM and the subsequent neonatal outcome of 71 delivered infants. All of these patients had pregnancies ranging from a gestational age of 19 weeks to 25 completed weeks. The aim of this study was to evaluate the potential risks and benefits associated with expectant management of patients with very early preterm PROM.

Material and methods

The study group included women who were seen with preterm PROM between Jan. 1, 1984, and Jan. 1, 1988. All of these patients had management at two of the perinatal referral centers in San Francisco—University of California San Francisco Medical Center and Children's Hospital.

All cases of preterm PROM from 19 to 25 weeks were examined. Of 128 cases, 58 were excluded from the study group. The criteria for exclusion were as follows: (1) cervical dilatation >3 cm on admission, (2) diagnosis of an incompetent cervix, (3) cerclage in place, (4) clinical evidence of amnionitis on admission, and (5) desire for elective termination of pregnancy.

Gestational age was determined by last menstrual period and/or ultrasonography, or both. All cases had documented rupture of membranes by Nitrazine testing, ferning, and/or pooling.

All patients without evidence of labor or amnionitis who desired to continue their pregnancies had expectant management consisting of hospitalization with bed rest. On admission all patients had a sterile speculum examination to document rupture of membranes and to obtain cervical cultures. No digital examinations were performed. Patients were monitored with frequent vital signs, complete blood counts, intermittent tokodynamometry, and fetal heart rate evaluation. Antenatal fetal assessment began at 25 weeks and consisted of daily fetal heart rate testing. Before 25 weeks, fetal heart tones were obtained with an electronic fetoscope at least two times each day. Amniotic fluid evaluations were obtained on a weekly basis in the majority of the patients. Patients were taken to labor and delivery for continuous monitoring if they experienced vaginal bleeding, uterine activity, or an abnormal fetal heart rate assessment.

Patients were monitored for the development of amnionitis. A presumptive diagnosis was made in most cases by the presence of two or more of the following criteria: (1) temperature >38° C, (2) persistent leukocytosis (white blood cell count >15,000/ml, (3) uterine tenderness or irritability, and (4) fetal tachycardia. Once the diagnosis of amnionitis was made, antibiotics were begun and labor was induced. All patients were cultured for group B streptococci and were treated if their cultures were found to be positive. Very few patients were given prophylactic antibiotics. In all cases steroids were withheld when there was any suspicion of amnionitis. All patients remained in the hospital until delivery occurred.

Intravenous tocolytics were used at the physician's discretion in patients who were undergoing expectant management and who began experiencing regular uterine contractions. Magnesium sulfate was administered as a 4 gm loading dose and maintained at 2 to 3 gm/hr as a continuous infusion. In a small number of patients terbutaline was begun at 10 μg/min and titrated depending on uterine activity. The intravenous tocolytics were discontinued with any of the following: (1) cessation of uterine activity, (2) evidence of amnionitis, (3) intolerance by patient, (4) cervical dilatation >4 cm. No tocolytics were given prophylactically.

Data regarding the patient's hospital course, as well as the patient's risk factors for PROM, were obtained from the maternal charts. The variables analyzed included gestational age at rupture and delivery, mode of delivery, indications for delivery, neonatal weights, and Apgar scores. These were obtained from both maternal and neonatal charts.

The neonatal hospital courses were carefully reviewed. The diagnosis of the degree of respiratory distress syndrome was made by initial ventilator settings, oxygen requirements, chest x-ray appearance, and overall length of time on the ventilator. The diagnosis of intraventricular hemorrhage was based entirely on ultrasonographic findings. The diagnosis of neonatal sepsis was based on positive blood cultures, neutropenia/leukocytosis, or thrombocytopenia. All of the surviving infants were evaluated with developmental testing until at least 1 year after delivery. Ten of the 45 (22%) surviving infants were followed up for a total of 3 years after delivery.

The frequency of respiratory distress syndrome, infectious morbidity, and the gestational prolongation from steroids and tocolytic therapy were examined. The results were analyzed by a χ^2 test to compare the frequency. The differences were considered to be significant for a p value of <0.05.

Results

The patients included in the study consisted of clinic and private patients, as well as patients transported to either of the referral institutions. The analysis was performed on patients who desired to continue their pregnancies and did not have evidence of labor or amnionitis. The patients' ages ranged from 18 to 38 years

Respiratory distress syndrome	37	52

with the mean being 29 years. Forty-five percent of the patients were primiparous, while 55% were multiparous. A history of previous preterm labor or PROM was identified in 11 patients (15%). Tobacco use was a factor in 20 patients (28%).

The gestational age of rupture of membranes ranged from 19 weeks to 25 completed weeks with the mean being 23.7 weeks. Twenty-nine percent of the patients had occurrence of rupture of membranes before 24 weeks of gestation. Rupture of membranes occurred at a gestational age of <20 weeks in only one patient. The gestational age at delivery ranged from 22 to 34 weeks with the mean being 26.6 weeks. The length of time from rupture of membranes to delivery ranged from 24 hours to 60 days. The mean latency period was 12 days. There was no correlation ($r = 0.24$) between gestational age at rupture of membranes and latency period (Fig. 1). The indications for delivery and the routes of delivery are listed in Table I. Delivery was achieved by the vaginal route in 53 (74%) of the patients. Three of these were vaginal breech deliveries and they were done at gestational ages of <25 weeks. Eleven of the 18 cesarean sections performed were classical. No cesarean sections were performed before a gestational age of 25 weeks.

Of the 70 patients reviewed in this study, 30 (43%) had clinical evidence of amnionitis. Fig. 2 shows the total number of patients within each latent period, as well as the number of patients in whom amnionitis developed with each latent period. This graph shows that 16 of the 28 patients (57%) who were delivered within the first 72 hours had amnionitis. Sixteen (53%) cases of amnionitis occurred within the first 7 days after rupture of membranes. The development of amnionitis after 14 days of rupture of membranes was low (6%). Twelve patients (17%) had a postpartum or postoperative endometritis (Table II). Five of the patients with endometritis had amnionitis before delivery. Eight of the 12 patients (66%) with endometritis had undergone

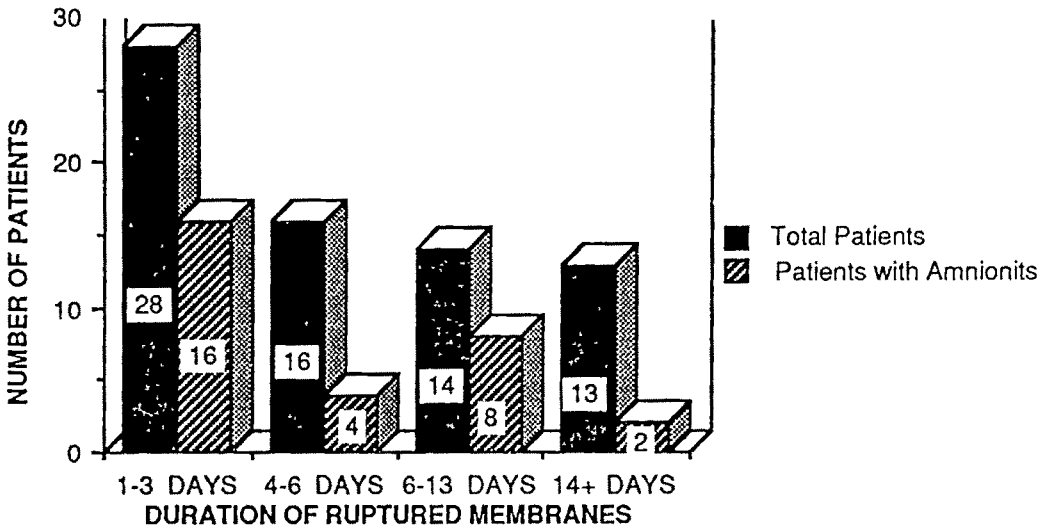

Fig. 2. Latency period of total patient population compared with latency period of those with amnionitis.

delivery by cesarean section. The average increase in hospital stays for those patients in whom endometritis developed was 2 days. Two patients had sepsis and one of them went on to experience septic shock, disseminated intravascular coagulopathy, and adult respiratory distress syndrome necessitating care in the intensive care unit. The patient had membrane rupture at 24 weeks with a latency period of 19 days. She had received steroids only (no tocolytics and no antibiotics). Seven (10%) patients required dilatation and curettage for management retained placenta. Three (4%) patients had postpartum hemorrhage; however, only one of them went on to require a transfusion. Two patients required blood transfusions after cesarean section. Perinatal outcome is shown in Table III. Neonatal survival in patients who had rupture of membranes from gestational ages of 19 to 22 weeks was 50%. Survival improved as the gestational age at rupture increased. When rupture occurred at 25 weeks of gestational age, 84% of the infants survived. Overall, from gestational ages of 19 to 25 weeks, 45 of 71 infants survived, resulting in a neonatal survival rate of 63%.

The neonatal mobidity was also evaluated (Table II). Twelve infants (17%) had sepsis. The diagnosis of sepsis was made by either positive blood cultures, elevated or low white blood cell counts, low platlet counts, or clinical symptoms. A grade 2, 3, or 4 intraventricular hemorrhage was apparent in 8 infants (11%). Respiratory distress syndrome was present in some degree in the majority of patients. Moderate to severe respiratory distress syndrome was present in 37 patients (52%). The average length of time on the ventilator was 39.4 days (±7.6 days) in the infants with severe respiratory distress syndrome.

There were 11 stillbirths and 15 neonatal deaths. The total perinatal mortality was 36%. All of the stillborn infants were delivered before 25½ weeks' gestation. The perinatal mortality in relation to gestational age at delivery is shown in Table IV. The average weight for stillbirths was 518 gm (± 180 gm). The majority of still-

Table IV. Distribution of gestational ages at delivery

births were thought to be secondary to abruptio placentae ($n = 5$) or were unknown ($n = 4$). Six of the 11 stillbirths were intrapartum deaths at a gestational age of <24 weeks. One of the stillbirths was secondary to a congenital cardiac anomaly incompatible with life. This infant was born at 25½ weeks. There were two other stillbirths that occurred at a gestational age of >25 weeks. One was associated with a massive abruptio placentae. This patient was taken for immediate classic cesarean section. The infant weighed 760 gm and received Apgar scores of 0 and 0. The other one was secondary to a cord prolapse in a 720 gm, 25 ½ weeks' gestation infant. By the time the prolapse was identified, no cardiac activity was noted on ultrasonography. There were 15 neonatal deaths, all of which occurred from 1 hour to 27 days of life. The clinical courses associated with neonatal deaths included sepsis ($n = 6$), respiratory distress syndrome ($n = 9$), asphyxia ($n = 3$), immaturity ($n = 2$), and anomalies ($n = 1$). Autopsies were performed on six of these infants. In only one case was the cause of death thought to be possibly related to hypoplastic lungs. This infant died after only 10 hours of life. Nine infants did not have autopsies, and three of them had clinical courses suggestive of hypoplastic lungs.

Thirty-one of the 45 survivors had normal neurologic and physical development at 1-year follow-up. The intact survival rate after 1 year was 68%. The survivors that did not fall into the "intact" group had a variety of abnormalities such as cerebral palsy ($n = 5$), chronic lung disease ($n = 4$), mental retardation ($n = 3$), blindness ($n = 2$), deafness ($n = 1$), and delayed motor development ($n = 6$).

There were no survivors at gestational ages of <24 weeks at delivery. At 24 weeks there was one survivor who subsequently had chronic lung disease and delayed motor development. There were no neonatal deaths or stillbirths at a gestational age of ≥27 weeks. Table IV depicts the distribution of gestational ages at delivery. The perinatal survival rates for pregnancies in which delivery occurred during the twenty-fifth and twenty sixth weeks were 44% and 71%, respectively. Perinatal survival for deliveries that occured at ≥27 weeks was 100% regardless of gestational age of rupture of membranes.

The management of a number of these pregnancies included measures such as the use of betamethasone and/or tocolytics in an uncontrolled manner at the discretion of the managing physician. Betamethasone was used in 34 patients (48%) (Table V). The average gestational age of the patients who received betamethasone was 25 weeks (±1.9 weeks) as compared with 23.8 weeks (±2.4 weeks) in patients who did not receive betamethasone. This difference in gestational age was not statistically significant. The difference in average birth weights between the two groups was statistically significant (990 ± 200 gm for the betamethasone group compared with 730 ± 110 gm for the nonbetamethasone group). When we reviewed the neonatal outcome, there were no significant differences in the incidences of respiratory distress syndrome, intraventricular hemorrhage, or sepsis between those who received steroids and those who did not. The maternal differences in the incidence of sepsis, amnionitis, and endometritis also were not statistically significant between the two groups.

The average time from rupture of membranes to delivery was 11.1 days (±4.0 days). Twenty-eight patients received intravenous tocolytics (Table VI). The latency period between those who received intravenous tocolytics (12.2 ± 3.8 days) and those who did not (10 ± 3.2 days) was not statistically significant. Again, the majority of patients were delivered of their infants in the first week and this was not affected by the use of tocolytics. It should be emphasized that the use of tocolytics was studied in a noncontrolled manner. Tocolytics were used in those patients having regular uterine contractions. The results revealed that the mean latency period in this group was not significantly less than the mean latency period of the group not having uterine contractions and therefore not receiving tocolytics. These results are not surprising. Neonatal outcome was not affected by the use of tocolytics. The incidences of respiratory distress syndrome, intraventricular hemorrhage, and sepsis were not statistically significant between the group who received tocolytics and the group who did not. Maternal outcome was relatively similar between the tocolytics group and the nontocolytics group. There were no statistically significant differences in the incidences of sepsis, pulmonary edema, endometritis, retained placentas, or postpartum hemorrhages between the two groups.

Comment

This article retrospectively reviews the outcomes of 70 patients with very early PROM. The patient popu-

*Mean gestation, 25 weeks. Mean birth weight, 990 gm.
† Mean gestation, 23.8 weeks. Mean birth weight, 730 gm.

lation within this study does not accurately represent the actual patient population with very early preterm PROM because of the fact that the majority of the patients were perinatal referrals. Management was expectant in all cases. Approximately half of all patients had management with the use of steroids and or tocolytics in an uncontrolled manner.

Because of the enormous advances in neonatal survival at very early gestations, there is a large increase in attention paid to expectant management of preterm PROM. The earliest study on this subject, published by Taylor and Garite[6] in 1984, revealed an overall neonatal survival of 24%. Beydoun and Yasin[7] had a slightly higher gestational age at rupture (19 to 29 weeks) and a higher perinatal survival of 31%. Moretti and Sibai[8] examined patients with PROM between 16 and 26 weeks and also had a perinatal survival of 31%. More recently, Bengtson and VanMarter,[9] in their review of preterm PROM between 19 and 26 weeks, had a survival rate of 51%. The latter authors, as in our study, examined only women with PROM who desired not to terminate their pregnancies and did not have evidence of labor or amnionitis.

In this study our neonatal survival was 66%. The intact neonatal survival was 42%. The intact survival reported from other studies is significantly lower than ours. Our infants underwent follow-up for 1 to 3 years. Previously, the longest reported follow-up of survivors of preterm PROM was < 1 year. The infants who survived with disabilities had a wide range of abnormalities, which included mental retardation, cerebral palsy, blindness, deafness, and motor delays. Some of the developmental problems were mild and some were extremely severe. The majority of severe developmental delays were among the infants in cases of membrane rupture before 24 weeks.

The infants' ultimate survival appeared to depend on the gestational age at delivery and not on the gestational age at rupture of membranes. This finding confirms the findings reported in other studies. Delivery before 24 weeks' gestation produced no survivors. Our apparently high stillbirth rate (15%) is comparable to that of the studies by both Moretti and Sibai[8] and Bengtson and VanMarter[9] which were 13% and 14% respectively. The stillbirth rates in the other two studies by Taylor and Garite[6] and Beydoun and Yasin[7] both exceeded 20%. We feel that our high stillbirth rate is a reflection of our nonaggressive management of pregnancies with a gestational age of <25 weeks.

Table VI. Tocolysis and latency period

	Tocolysis	*No tocolysis*	*p Value*
No.	28	42	<0.001
Mean (days)	12.2	10	NS
>24 hr	7 (25%)	8 (19%)	NS
>48 hr	8 (28%)	4 (33%)	NS
>1 wk	10 (35%)	18 (42%)	NS
Reached 32 wk	3 (10%)	2 (6%)	NS

The maternal findings of a 43% incidence of amnionitis, a 17% incidence of endometritis, and a 2% incidence of sepsis are comparable to those in other studies. In our study, however, there were no serious long-term maternal sequelae. Neonatal complications in this study were frequent. The incidence of severe respiratory distress syndrome was 52%. This was not reduced by either betamethasone or tocolytics. Other authors[9] reported similar findings. The incidence of sepsis was 17%, and again this was not altered by the use of betamethasone or tocolytics. Intraventricular hemorrhage occurred in 11% of the infants born. No improvement in the incidence of intraventricular hemorrhage was noted with either betamethasone or tocolytics. This finding also has been seen by other authors.[10]

Only 1 of 70 infants was thought to have hypoplastic lungs. This is similar to the incidence in the study of Moretti and Sibai,[8] in which only 1 of 118 infants was noted to have hypoplastic lungs. Beydoun and Yasin[7] had no cases of hypoplastic lungs. In contrast, Taylor

and Graite[6] reported that 6 of their 8 neonatal deaths were given a probable diagnosis of hypoplastic lungs. In our study the confirmed diagnosis of hypoplastic lungs in only one infant may be misleading because of the low number of autopsies performed in these patients.

In summary, our results, as well as data from previous studies, provide information concerning the possible risks and benefits of expectant management of very early preterm PROM. This study reveals that the neonatal outcome in patients with midtrimester rupture of membranes is not as dismal as has been portrayed in the past. Our results demonstrate that, as neonatal care has continued to improve, we can counsel our patients with preterm PROM and give a more positive picture of neonatal survival.

The goal of all pregnancies is to have safe delivery of a healthy infant. Expectant management of midtrimester PROM is a reasonable option for patients as long as they are aware of both their potential risks of maternal morbidity and their chances of delivering a normal infant.

Double-blind comparison of intravaginal prostaglandin E_2 gel and "chip" for preinduction cervical ripening

Carl V. Smith, MD,[a] William F. Rayburn, MD,[a] Robert E. Connor, RPh,[b] Glen R. Fredstrom, RPh,[b] and Corinne B. Phillips, MD[a]

Omaha, Nebraska

The intravaginal application of prostaglandin E_2 for preinduction cervical ripening has proved to be advantageous in the management of patients with an unfavorable cervix. The purpose of this double-blind randomized investigation was to compare the efficacy and safety of two methods of prostaglandin E_2 delivery. Patients who were to have preinduction cervical ripening because of an unfavorable cervix (Bishop score ≤4) were randomly assigned to be given a single dose of prostaglandin E_2 as either 2.5 mg of gel or a 3.0 mg "chip" intravaginally in a placebo-controlled manner. Sixty-nine patients received the active prostaglandin E_2, 34 in the gel group and 35 in the "chip" group. The groups were similar in maternal age, race, parity, gestational age, and initial Bishop score. Both forms of prostaglandin E_2 were easy to administer and helpful in priming an unfavorable cervix. The need for, duration of, and maximum dose of oxytocin were similar in both groups. Cesarean delivery because of failed induction occurred in 5 of 35 (14.3%) patients receiving a "chip" and 4 of 34 (11.8%) receiving the gel. However, patients receiving a "chip" experienced a 20% (7/35) incidence of hyperstimulation, compared with 2.9% (1/36) in those receiving the gel ($p < 0.05$). The only case requiring immediate cesarean delivery because of intractable uterine hyperstimulation received a "chip." We conclude that both methods were effective for cervical ripening, but the lower incidence of uterine hyperstimulation seen with the gel would suggest that it is preferable to the "chip." (AM J OBSTET GYNECOL 1990;163:845-7.)

Key words: Prostaglandin E_2, cervical ripening, induction of labor

Many randomized studies have shown the value and safety of low-dose prostaglandin E_2 (PGE_2) therapy in promoting preinduction cervical ripening and lowering the need for oxytocin during labor.[1-3] The optimal dosage and method of intravaginal delivery remain controversial.[4]

The PGE_2 intravaginal preparation used most commonly is a 1 to 4 mg gel.[4,5] Macer et al.[6] have reported on the use of intravaginal prostaglandin E_2 "chips," prepared by cutting a standard 20 mg PGE_2 suppository into six equal parts. The principal advantage of the "chip" is its widespread availability at labor and delivery units and the lack of compounding requirements in the pharmacy.

The purpose of the current investigation was to compare the effectiveness and side effects of intravaginal PGE_2 "chips" to those of gel in a double-blind randomized manner.

Material and methods

Approval was granted by our Institutional Review Board. Patients deemed to require induction of labor and having an unfavorable cervix (Bishop score ≤4), intact membranes, and a cephalic presentation were considered candidates for the investigation.[7] After giving informed consent, each subject underwent fetal surveillance with nonstress testing and ultrasonographic assessment of amniotic fluid volume. Additional requirements for enrollment included a reactive nonstress test and normal amount of amniotic fluid (defined by an amniotic fluid index >5).[8]

Each subject received both the gel and "chip" simultaneously, with only one preparation containing PGE_2. Whether PGE_2 was found in the gel or "chip" was determined by our pharmacists using a random numbers table. A single pharmacist prepared the "chips" by cutting a 20 mg suppository (Prostin, The Upjohn Co., Kalamazoo, Mich.) cross-sectionally into six equal parts, each containing 3 to 3.5 mg of PGE_2. An attempt was made to assure that all six "chips" were of uniform size and shape. No attempt was made to compare weights. The same pharmacist prepared the gel by combining methylcellulose with 2.5 mg of PGE_2.[4] It was then placed in a 3 ml syringe, which was frozen until its use.

The portio vaginalis of the cervix was cleansed of

Table I. Comparison of effectiveness of intravaginal PGE_2 "chips" and gel

	Chip (n = 35)	*Gel (n = 34)*	*p Value*
Bishop score change ≥3 after PGE_2	17 (48.6%)	21 (61.8%)	NS
Bishop score ≥5 after PGE_2	23 (65.7%)	27 (64.7%)	NS
Spontaneous labor	12 (34.3%)	12 (35.3%)	NS
Duration of oxytocin (hr)	10.9 ± 7.5	7.4 ± 4.0	NS

Duration of labor (hr)	13.9 ± 7.4	11.5 ± 7.8	NS
Cesarean section because of failed induction	5 (14.3%)	4 (11.8%)	NS
Hyperstimulation	7 (20.0%)	1 (2.9%)	0.05

excess mucus with a long cotton applicator. The patient was then given 2.5 ml of the gel (with a 16-gauge intravenous catheter) in the posterior fornix followed by placement of the "chip" inside the vaginal introitus.[4, 6] Uterine activity and the fetal heart rate were monitored continuously for a minimum of 2 hours while the patient remained in a semirecumbent position. If contractions were less frequent than two every 10 minutes and the fetal heart rate was normal, the patient was allowed to ambulate. Those patients who had signs of uterine hyperstimulation (previously unrecorded uterine contractions leading to decelerations of the fetal heart rate or sustained, excessive discomfort) were treated with intravenous or subcutaneous doses of 250 mcg of terbutaline.

Subjects were reexamined in approximately 12 hours (usually at 7 AM) and a post-PGE_2 Bishop score was assigned. If the patient was not already in active labor (regular uterine contractions with a cervical dilatation ≥3), we began intravenous oxytocin for augmentation or induction of labor. Guidelines recommended by the American College of Obstetricians and Gynecologists[9] were followed. An amniotomy was customarily performed once the cervix dilated to 3 cm.

The duration of labor was defined as the time from onset of regular uterine contractions every 3 minutes, either spontaneously or oxytocin-induced, until vaginal delivery. Cesarean delivery was considered in cases of failed induction if the cervix did not dilate beyond 3 cm despite adequate labor for at least 8 hours. Outcome comparisons included the following parameters: Bishop scoring before and after prostaglandin administration, percentage of patients entering spontaneous labor, duration of labor, maximum rate of oxytocin infusion, incidence of uterine hyperstimulation, route of delivery, Apgar scores, and umbilical cord gas determination.

After all the data were recorded, the code was broken for comparative purposes. Proportional data were analyzed by Fisher's exact test. Averaged data were reported as mean ± 1 SD and analyzed with a two-tailed Student t test. A p value of <0.05 was considered statistically significant.

Results

Sixty-nine patients agreed to enrollment and were randomly assigned to receive active PGE_2 in either the "chip" (35 patients) or the gel (34 patients). The groups were statistically similar with respect to maternal age (23.3 ± 5.2 vs 23.3 ± 3.6 years), parity (1.0 ± 1.4 vs 0.57 ± 0.07), and pre-PGE_2 Bishop score (3.1 ± 1.1 vs 3.3 ± 0.8). Gestational age, race, and indications for induction (postdates, hypertension, suspected intrauterine growth retardation, and diabetes) were also similar.

Both groups of patients responded favorably to the administration of prostaglandin. There were no statistically significant differences between the groups in post-PGE_2 Bishop score change, successful induction of labor, and cesarean delivery because of failed induction. The need for, duration of, and maximum dose of oxytocin also were similar between the treatment groups. Approximately half of the patients in each group who required oxytocin received it only for augmentation of spontaneous labor. One patient receiving the "chip" experienced mild nausea with vomiting. Fever and diarrhea were not seen in any study patient.

Table I compares the effects of the two types of administration. A total of eight cases of uterine hyperstimulation were present. The rate of hyperstimulation in the gel group was 2.9% (one case) compared with 20.0% (seven cases) in the "chip" group. This difference was statistically significant ($p < 0.05$). This condition began within the first hour after instillation and appeared as very frequent (more than 5 in 10 minutes) and often strong contractions. Administration of terbutaline was successful in normalizing uterine contractions in 87.5% (seven of eight cases). The normalization usually began withinm 5 minutes after tocolytic therapy, regardless of hyperstimulation pattern. The one case in which contractions persisted despite multiple doses of terbutaline required eventual cesarean delivery. The infant did well.

Three cases in the "chip" group and one in the gel group required cesarean delivery because of fetal distress. All occurred after several hours of labor and appeared unrelated to PGE_2 administration. The out-

comes of all infants in this study were favorable. When compared with those patients recieving an active "chip," patients receiving gel were delivered of infants that were similar in birth weights (3450 ± 670 vs 3312 ± 554 gm). Differences between the "chip" and gel groups also were not statistically significant with respect to the frequency of 1-minute Apgar scores <7 (n = 3 or 8.6% vs n = 3 or 8.8%) and 5-minute Apgar scores <7 (n = 2 or 5.7% vs 0). No infant in either group had an umbilical artery pH < 7.20.

Comment

The optimal method for preinduction cervical ripening should be safe, efficacious, noninvasive, and free of troublesome side effects. PGE_2 gel has been used successfully by many investigators and appears to be the drug of choice for this clinical situation. This agent is thought to split, separate, and dissolve tightly woven bundles of collagen fibers in the cervix. The use of PGE_2 gel in some institutions has been hampered by the reluctance of pharmacists to compound a Food and Drug Administration nonapproved drug into a vehicle that is applied intravaginally. PGE_2 "chips" obviate the need for pharmacy involvement.

The present study represents what we believe to be the first comparison between these two methods of PGE_2 administration. The two groups of patients in this double-blind study were similar with respect to their demographics and their indication for delivery, permitting an accurate comparison of the two groups. Both methods of prostaglandin administration appeared to yield equivalent changes in the Bishop score and were successful in promoting cervical ripening. The overall incidence of vaginal delivery reported here (86% to 88%) compares favorably with other reports.[4]

Although the primary aim of low-dose PGE_2 therapy is cervical ripening, uterine contractions occur coincidentally but are usually "silent" or mild. Of concern is excessive and undesired stimulation, which we defined as contractions becoming so frequent as to cause fetal or maternal distress and warrant tocolytic therapy. The incidence of uterine hyperstimulation in the present investigation varied from 2.9% in the gel group to 20% in the "chip" group. The incidence of hyperstimulation in the gel group was similar to our prior experience and to reports in the world literature. Hyperstimulation usually occurred within several minutes after PGE_2 administration, since absorption velocities are rapid.[10] It was rapidly reversed with subcutaneous terbutaline therapy.

We were surprised to find such a high frequency of uterine hyperstimulation in the "chip" group. The reasons for this unanticipated finding are speculative but may relate to a slightly higher dose of PGE_2 in the "chip" or difficulties in assuring that all "chips" were of equal size. If we assume that the "chips" were of equal size and shape, the most likely explanations for these results are unequal distribution of the drug within the suppository and different rates of absorption between "chips." Because of the rate of hyperstimulation, we decided to discontinue the study, since we saw no distinct advantage of the "chip" over the gel.

On the basis of these observations, we conclude that the use of PGE_2 gel is preferable to "chips" of PGE_2 for the promotion of cervical ripening in patients with an obstetric indication for delivery and an unfavorable cervix. Other adverse effects after PGE_2 administration, during labor and immediately postnatally, were not found regardless of the presence or absence of uterine hyperstimulation. Close monitoring remains necessary so that tocolytic therapy can be instituted early and rapidly reverse any excessive PGE_2-induced contractions.

Vaginal breech delivery: A five-year prospective evaluation of a protocol using computed tomographic pelvimetry

Stefanie Schupp Christian, MD, Kim Brady, MD, John A. Read, MD, and Jerome N Kopelman, MD

Tacoma, Washington

In 1983 a protocol was established at our institution that used computed tomographic pelvimetry to evaluate patients presenting with a singleton term frank breech fetus for an attempt at vaginal delivery. The criteria for a trial of labor were singleton fetus, term gestation (37 to 42 weeks' gestation from the first day of the last menstrual period), frank breech presentation, estimated fetal weight 2000 to 4000 gm, non-extended fetal head, and adequate computed tomographic pelvimetry. Two digital radiographs and a tomographic cross-section were taken of each patient, i.e., an anteroposterior view, a lateral view, and an axial section through the femoral head at the level of the fovea capitalis. Adequate pelvimetry was defined as: anteroposterior diameter of the inlet ≥10.0 cm, transverse diameter of the inlet ≥11.5 cm, transverse (interspinous) diameter of the midpelvis ≥9.5 cm, and posterior sagittal diameter of the midpelvis ≥4.0 cm. The purpose of this prospective analysis was to determine the obstetric and perinatal outcome of those breech fetuses that were evaluated with these criteria during the study period of January 1984 through July 1989. During this period the incidence of breech deliveries at our institution was 2.71% (394/14,542). Of these 394 breech deliveries, 122 patients underwent computed tomographic pelvimetry. Eighty-five patients had adequate pelvimetry, fulfilling the protocol criteria, and formed the study group. Eighty-one percent (69/85) of the study group had successful vaginal deliveries (group 1). Nineteen percent (16/85) required cesarean delivery after a trial of labor (group 2) (10 with fetal distress and six with arrested labor disorders). Of the 37 patients who had inadequate computed tomographic pelvimetry and underwent cesarean delivery without a trial of labor (group 3), 54% (20/37) had an extended fetal head, 21.6% (8/37) had an inadequate transverse diameter of the inlet, 13.5% (5/37) had an inadequate midpelvic posterior sagittal measurement, and 10.8% (4/37) had an inadequate interspinous diameter. Perinatal outcome including Apgar scores, cord gases, length of hospital stay, neonatal complications, was evaluated. No difference in infant complications was noted between the group delivered vaginally and the groups delivered abdominally. The only maternal complications in our study group were chorioamnionitis, endomyometritis, and postpartum anemia. There were no significant differences in the incidence of chorioamnionitis among the three groups of patients. There was a higher incidence of endomyometritis in group 2 ($p < 0.01$), than in groups 1 and 3. Interestingly, group 3 experienced a significantly greater incidence of postpartum anemia ($p < 0.01$) when compared with groups 1 and 2. The total radiation exposure to the fetus from computed tomographic pelvimetry is estimated to be approximately 82 mrad, whereas with conventional x-ray pelvimetry the infant may be exposed to as much as 500 to 1100 mrad. Our findings document that computed tomographic pelvimetry is an effective tool in the assessment for vaginal delivery of the singleton term frank breech fetus. (Am J Obstet Gynecol 1990;163:848-55.)

Key words: Breech delivery, pelvimetry, computed tomography

Before the late 1950s, the vaginal route was the method of delivery for breech fetuses. In 1956, Hall and Kohl[1] first suggested routine cesarean delivery in an effort to reduce the excessive perinatal morbidity and mortality then associated with vaginal breech deliveries. Shortly thereafter, Wright[2] reaffirmed this recommendation. Since that time, the cesarean section rate for breech delivery has risen from 4% to 10% up to 80% to 90%.[3] This increase in abdominal deliveries, however, has been associated with an increased risk of maternal morbidity. Furthermore, the increased rate of cesarean deliveries has not resulted in a concomitant improvement in neonatal and infant outcome.[4] Over the past 20 years, much attention has been focused on the reevaluation of vaginal delivery of the breech fetus.

Numerous investigations have demonstrated the

safety of vaginal delivery for selected term frank breech infants.[5-7] Huchcroft et al.,[8] in a long term follow-up investigation, compared early outcome parameters with behavioral and health criteria at age 2½ and 8½ years. No differences existed between breech babies delivered vaginally and those who were products of cesarean sections. Several investigators[9, 10] have demonstrated that vaginal delivery of selected term breech infants, using strict management protocols including conventional x-ray pelvimetry, significantly improved perinatal outcome when compared with that of breech deliveries managed without benefit of similar protocols. Accordingly, most specialists in maternal-fetal medicine now advocate a trial of labor for the selected breech fetus.[11]

Practical application of conventional x-ray pelvimetry, however, is limited by the relatively high radiation dose to which the infant is exposed, as well as wide variation in film quality. In 1985, Gimovsky et al.[12] suggested that measurements made by computed tomographic pelvimetry might be more precise and reproducible than those obtained by conventional x-ray film.

In 1986, Kopelman et al.[13] published the results of a protocol using computed tomographic pelvimetry to assess the term breech fetus for vaginal delivery. Results of this preliminary investigation demonstrated the utility and safety of such a protocol. The purpose of this prospective investigation is to report our 5-year experience with computed tomographic pelvimetry in the management of the term frank breech fetus.

Material and methods

This investigation was performed at Madigan Army Medical Center during the period Jan. 1, 1984, through July 31, 1989. All singleton term (37 to 42 weeks' gestation) frank breech fetuses were eligible for enrollment. Gestational age was determined by a minimum of two of the following criteria: first day of last menstrual period, Doptone with audible heart rate by 12 weeks' estimated gestational age, fetoscopic confirmation of fetal heart rate by 20 weeks' estimated gestational age, fundal height appropriate for gestational age during second trimester, or ultrasonography performed during first or second trimester. Informed written consent for diagnostic studies was obtained from patients in accordance with criteria established by our institutional review committee. All obstetric patients who were identified as having fetuses in breech presentation underwent ultrasonographic examination to assess estimated fetal weight and exclude the presence of multiple gestation, placenta previa, and/or congenital anomalies. At 37 weeks' estimated gestational age or beyond, patients whose ultrasonographic estimated fetal weights[14] were between 2000 and 4000 gm were scheduled for a nonstress test (NST). If the NST was reactive, an external cephalic version was attempted. If the version was unsuccessful, the patient was discharged after a repeat reactive NST with instructions to return for weekly NSTs and follow-up visits in our routine obstetrics clinic. On presentation in labor, confirmation of frank breech presentation was made via ultrasonography, and a repeat ultrasonographic estimate of fetal weight[14] was obtained. If the estimated fetal weight met our criteria, the patient was transported, after documentation of a reassuring external fetal heart rate tracing, to the radiology department for computed tomographic pelvimetry. Interpretation of the computed tomographic pelvimetry was performed by an experienced member of the obstetrics house staff.

The computed tomographic scanner used during the study period was a General Electric model 8800 (General Electric Medical Systems, Milwaukee). As in the preliminary study by Kopelman et al.,[13] the method for pelvimetric measurements was that originally described by Federle et al.[15] Throughout the computed tomographic study, the patient was maintained in a dorsal supine position. Two digital radiographs and a cross-sectional tomograph were taken: an anteroposterior view, a lateral view, and an axial section through the femoral head at the level of the fovea capitalis. The anteroposterior view served as a fetogram (Fig. 1), allowing determination of the attitude of the fetal head. The transverse diameter of the pelvic inlet was measured from this film. The level of the fovea capitalis was obtained and used to determine the level of the axial section. The transverse diameter of the midpelvis was then measured from this axial section (Fig. 2). The lateral view was used to measure the anteroposterior diameter of the pelvic inlet (Fig. 3) and the posterior sagittal diameter of the midpelvis (Fig. 4). The lateral radiograph also permitted visualization of the contour of the sacrum. On completion of the pelvimetry study patients were considered eligible for vaginal delivery if all the following criteria were fulfilled: frank breech presentation, estimated fetal weight 2000 to 4000 gm, nonextended fetal head, anteroposterior diameter of inlet $\geq$10.0 cm, transverse diameter of the inlet $\geq$11.5 cm, transverse (interspinous) diameter of the midpelvis $\geq$9.5 cm, and a posterior sagittal diameter of the midpelvis $\geq$4.0 cm. These measurements represent a composite of critical values described by Benson et al.[6] and Collea et al.[7]

The radiation dose absorbed by the fetus from each of the two digital radiographs is approximately 22 mrad. The dose from the axial section is approximately 38 mrad. This results in an estimated radiation exposure of 82 mrad.[17]

The Statview II computer software statistical package (Abacus Concepts, Inc., Berkeley, Calif.) was used for analysis of data. A χ^2 test was used to compare the

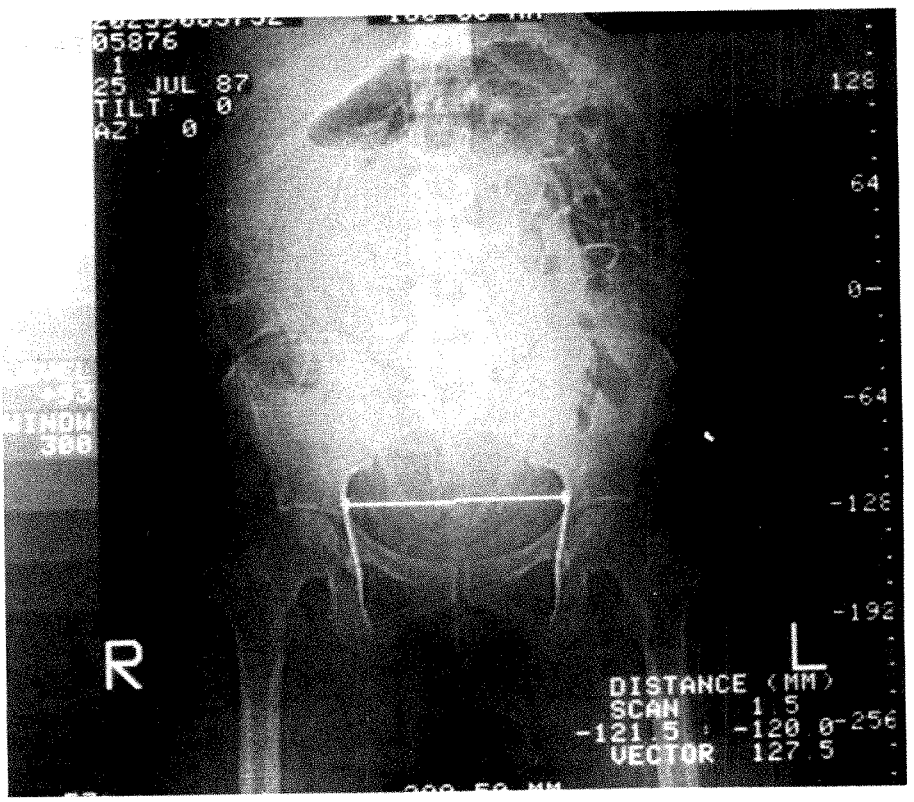

Fig. 1. Anteroposterior digital radiograph of the pelvis as a fetogram, allowing determination of the attitude of the fetal head and measurement of transverse diameter of the pelvic inlet.

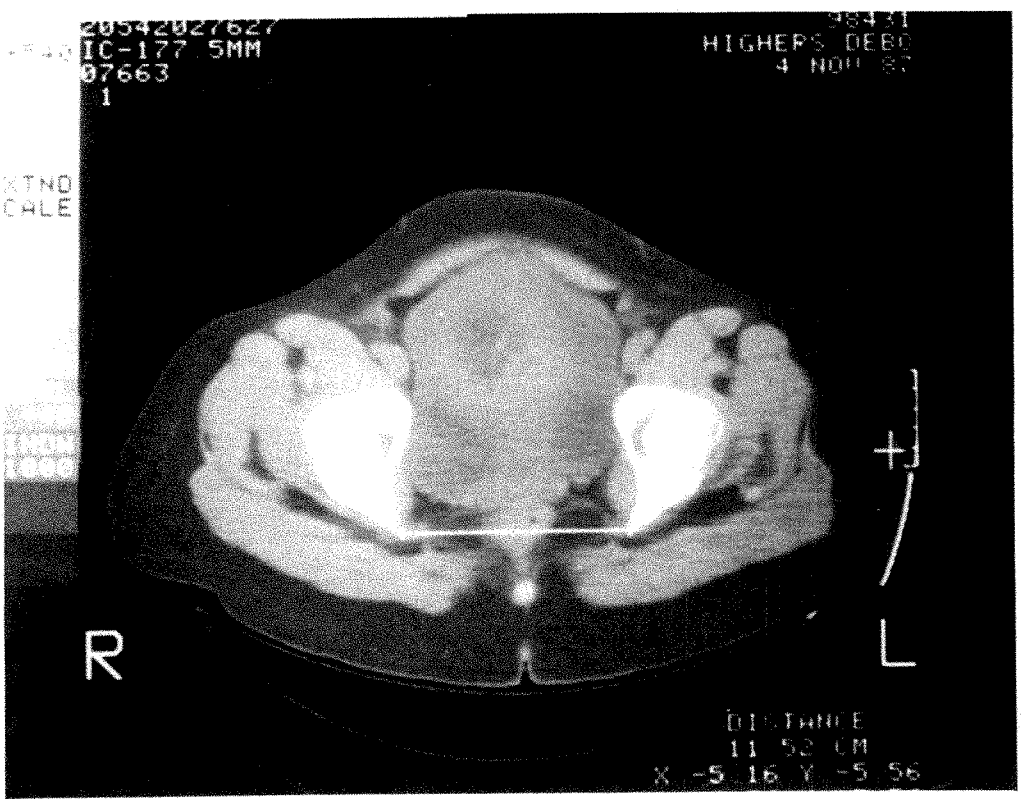

Fig. 2. Axial computed tomographic section taken at the level of fovea capitalis, which permits measurement of transverse diameter of the midpelvis.

Fig. 3. The lateral view is used to measure both anteroposterior diameter of the pelvic inlet (Fig. 3) and posterior sagittal diameter of the midpelvis (Fig. 4).

difference in maternal morbidity between the patients delivered vaginally and those delivered abdominally. The Kruskal-Wallis test was used to analyze Apgar scores. The Scheffé F test was used to evaluate arterial and venous umbilical cord pH differences between breech fetuses delivered vaginally and those delivered abdominally. We considered a probability value <0.05 to be statistically significant.

Results

During the study period the incidence of breech delivery was 2.7% (394 of 14,542 deliveries). Of these 394 breech deliveries, 159 (40.4%) fulfilled criteria for gestational age, ultrasonographic fetal weight, and frank breech presentation, thus making them eligible for computed tomographic pelvimetry. Computed tomographic pelvimetry was obtained on 122 (77%) of the 159 eligible frank breech fetuses. The remaining 37 patients could not undergo the procedure because of advanced cervical dilation or rapidly progressing labor at the time of presentation. Eighty-five of the 122 patients who underwent computed tomographic pelvimetry were determined to have adequate pelvimetric measurements. These women formed a study population consisting of two groups. Group 1 consisted of those women who were successfully delivered vaginally. Group 2 consisted of those women requiring cesarean delivery after an unsuccessful trial of labor. The remaining 37 patients (group 3) had inadequate pelvimetry measurements and required cesarean delivery. Reasons for inadequate pelvimetry were extended fetal head, 54% (20/37); inadequate transverse diameter of the inlet, 21.6% (8/37); inadequate posterior sagittal diameter of the midpelvis, 13.5% (5/37); and inadequate interspinous diameter, 10.8% (4/37). Fig. 5 summarizes the clinical outcome of all patients presenting in labor with breech fetuses.

Of the 85 patients with adequate pelvimetry, 81.2% (69/85) achieved vaginal deliveries (group 1) and 18.8% (16/85) had cesarean deliveries after a trial of labor (group 2). Obstetric indications for abdominal delivery included 10 for fetal distress and six for arrested labor disorders. The diagnostic criteria of Friedman and Sachtleben[18] for arrested labor disorders were strictly followed. Table I depicts the characteristics of those patients who had adequate pelvimetric values but ultimately required cesarean delivery because of arrested labor.

For purposes of evaluating maternal morbidity and neonatal outcome, the patient-infant pairs were divided into the same groups mentioned above. Table II displays the median Apgar scores, as well as the mean

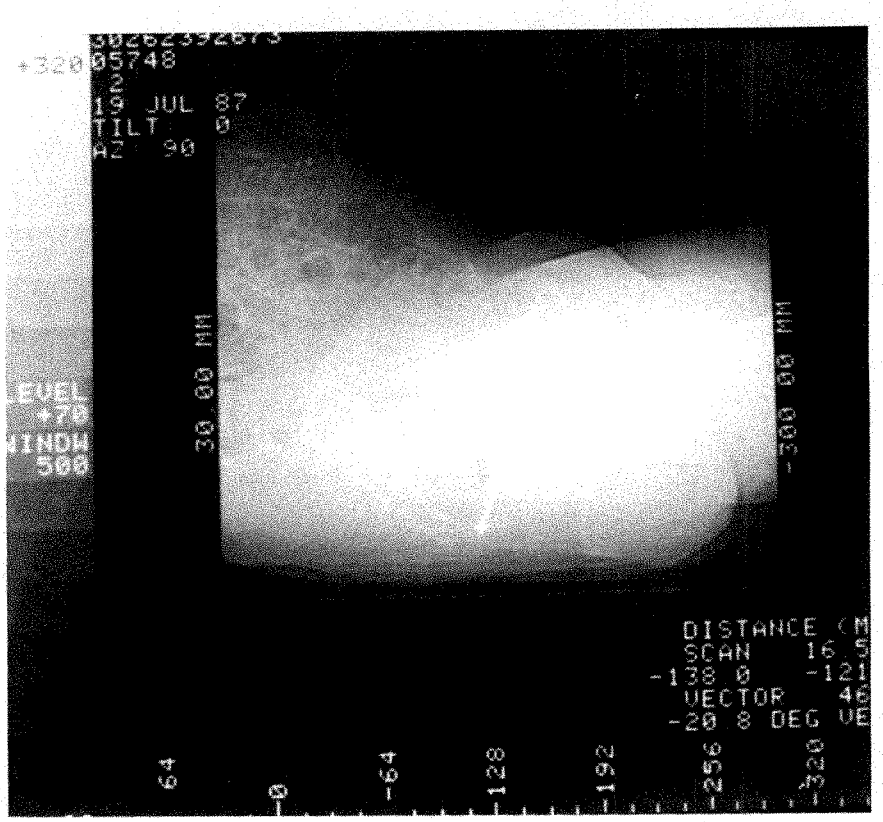

Fig. 4. The lateral view allows not only measurement of the posterior sagittal diameter of the midpelvis but visualization of the contours of the sacrum as well.

*Additional complications included one spinal headache and one wound separation.

arterial and venous cord pH values. Table III demonstrates the distribution of maternal complications. Chorioamnionitis was defined as the presence during labor of a maternal temperature >100.4°F, with or without associated fetal tachycardia and or uterine tenderness. Endomyometritis was defined as maternal temperature >100.4°F at any time after vaginal delivery or after 24 hours in cesarean deliveries. In both instances absence of other identifiable sources of infection was required to make the diagnosis.

Comment

Computed tomographic pelvimetry has been reported to be as reliable as conventional x-ray pelvimetry in predicting the likelihood of successful vaginal delivery.[12, 13] Moreover, computed tomographic pelvimetry has several advantages when compared with conventional x-ray pelvimetry. First, because of differences in technique and improved film quality, pelvimetric measurements are more easily interpreted and readily standardized with computed tomographic technology. With x-ray pelvimetry, variations in the skill and level of experience of the x-ray technician can result in errors, requiring repeat studies. This can be avoided with computed tomographic pelvimetry. Computed tomographic pelvimetry exposes the patient and fetus to a significantly lower radiation dose. The dose absorbed by the fetus from each of the two digital radiographs is approximately 22 mrad. The dose from the axial section is approximately 38 mrad. Computed tomographic pelvimetry results in a total fetal dose of approximately 82 mrad.[17] In contrast, conventional x-ray

pelvimetry exposes the infant to between 500 and 1100 mrad.[19] Finally, computed tomographic pelvimetry requires neither postural change nor awkward ruler placement and is much more comfortable for the patient than is conventional x-ray pelvimetry.

In 1986, Kopelman et al.,[13] using our current protocol, evaluated 32 singleton term breech pregnancies for trial of labor. Of the 17 patients who fulfilled the criteria for attempted vaginal delivery, 82.4% (14/17) were delivered vaginally. These original results, as well as our current findings, are similar to or better than those obtained with conventional x-ray pelvimetry. Collea et al.[7] found that 82% of their study group who met the criteria for trial of labor went on to deliver vaginally. Gimovsky et al.[12] found a 66% vaginal delivery rate among patients approved for trial of labor. All three groups of investigators[7, 12, 13] found no increase in perinatal morbidity or mortality for vaginal delivery of the breech fetus when careful selection criteria were used.

In this study, which expands the original study group used by Kopelman et al., 81.2% (69/85) of our study group with adequate computed tomographic pelvimetry were delivered vaginally. This is the largest prospective investigation to date assessing computed tomographic pelvimetry in the evaluation of the selected term frank breech fetus. Our success rate for vaginal breech delivery (81.2%) was accomplished with no significant maternal or perinatal complications. Our results compare favorably to the success rate previously reported from our institution with conventional x-ray techniques. Between 1980 and 1984, Watson and Benson[5] retrospectively evaluated 254 term breech deliveries at Madigan Army Medical Center. In their study 75.8% (69/91) of patients with an estimated fetal weight <4000 gm and adequate or borderline adequate x-ray pelvimetry were delivered vaginally.

There were no clinically significant differences in perinatal outcomes among the three groups of patients when compared for Apgar scores, venous cord gases, duration of hospitalization, or discharge diagnoses recorded in the infants' charts. The statistically lower mean umbilical cord artery pH in the vaginally delivered group is not unexpected. The mean umbilical cord venous pH is well within the accepted normal range. Although our data document a lower umbilical cord artery pH, evidence already exists in the literature that our excellent median 5-minute Apgar score is predictive of no long-term ill effects.[8] Thus, despite the findings of a statistically lower mean umbilical cord artery pH in breech fetuses delivered vaginally, it is unlikely to be of any clinical significance and probably represents acute cord compression during the second stage of labor. Since umbilical cord venous pH is a good indirect measurement of placental function, our data suggest that there was no difference in placental function between those breech infants delivered vaginally and those delivered abdominally. Thus, our data support the findings of other investigators that there was no difference in fetal outcome between infants delivered vaginally and those delivered abdominally.

As expected, uterine infection after cesarean delivery was more common among those patients who labored and ultimately required abdominal delivery ($p < 0.01$) than among those patients who were delivered vaginally. Of note is the significantly higher incidence of postpartum anemia ($p < 0.01$) in the group who, because of inadequate pelvimetry, underwent cesarean delivery without experiencing a lengthy labor. This finding is most likely attributable to an unlabored lower uterine segment and resultant greater intraoperative blood loss.

Our overall incidence of 2.7% breech deliveries is lower than the usually reported incidence of 3% to 4% and is directly attributable to our active external cephalic version protocol for all term breech presentations. In 1987, Robertson et al.[20] reported a success rate of 67% for external cephalic version at our institution.

In conclusion, this series is the largest investigation to date that evaluates the outcomes of selected vaginal term frank breech deliveries by means of computed tomographic pelvimetry. The 81.2% rate of successful vaginal breech delivery with our protocol is noteworthy because there were no significant increases in maternal or perinatal complications. This protocol involves very little risk to the fetus and avoids the maternal morbidity associated with unnecessary cesarean delivery. Our findings document that computed tomographic pelvimetry is an effective tool in the assessment for vaginal delivery of the singleton term frank breech fetus.

The incidence of significant fetomaternal hemorrhage in patients undergoing cesarean section

Nathalie Feldman, MD, Amanda Skoll, MD, and Baha Sibai, MD
Memphis, Tennessee

To determine the incidence of fetomaternal hemorrhage in patients undergoing cesarean section, Kleihauer-Betke tests were performed in the immediate postoperative period on 199 parturients. Some degree of hemorrhage was detected in 18.5% of patients, with 2.5% demonstrating >30 ml of fetal blood. Comparison of groups on the basis of indication for cesarean delivery revealed no difference in rates of fetal hemorrhage. Because patients with >30 ml of fetal blood would not be adequately protected from Rh sensitization by the standard 300 μg dose of Rh immune globulin, we recommend screening all Rh-negative patients undergoing cesarean section for the presence of significant fetomaternal hemorrhage. (AM J OBSTET GYNECOL 1990;163:855-8.)

Key words: Fetomaternal hemorrhage, Rh sensitization

The widespread use of postpartum and antepartum Rh immune globulin has significantly reduced the incidence of hemolytic disease of the newborn as a result of maternal Rh isoimmunization. However, there remains a small number of patients (0.2% to 1%) who become sensitized at the time of delivery,[1] perhaps as a result of significant fetomaternal hemorrhage occurring at that time. Because the standard dose of Rh immune globulin (300 μg) covers up to 30 ml of fetal hemorrhage,[2] any degree of fetomaternal hemorrhage above this threshold could result in sensitization.

Previous studies have suggested several different clinical factors that may increase the risk of significant fetomaternal hemorrhage including forceps delivery, manual removal of the placenta, multiple gestation, fetal distress, and cesarean section.[3-7] However, there is no consensus as to which, if any, of these factors can identify a group of patients who should be tested at the time of delivery to quantify the degree of fetomaternal hemorrhage.[8-9]

The purpose of this study was to determine the incidence of significant fetomaternal hemorrhage in patients undergoing cesarean delivery at our institution to decide whether routine quantification of fetomaternal hemorrhage was justified to identify patients who require extra Rh immune globulin.

Material and methods

The E. H. Crump Women's Hospital is a tertiary care center affiliated with the University of Tennessee, Memphis, serving the population of Memphis, western Tennessee, and parts of Arkansas, and Mississippi. The study protocol was reviewed and approved by the Institutional Review Board of the University.

The study population consisted of 200 consecutive patients undergoing cesarean section for any indication. In the immediate postoperative period (usually within 1 hour, but occasionally as long as 4 hours post operatively), 5 ml of blood was drawn from the antecubital vein into a vacuum tube containing 0.05 ml of 15% ethylenediaminetetraacetic acid. All samples were then refrigerated until a Kleihauer-Betke acid elution test[10] could be performed to quantify the number of fetal cells present. All tests were performed within 24 hours of specimen collection by the same technician. One specimen was lost, leaving 199 patients for analysis.

The total amount of fetal blood present in the maternal circulation at the time of sampling was determined by the formula:

$$\frac{\text{Number of fetal cells}}{\text{Number of maternal cells}} = \frac{\text{Volume of fetal hemorrhage}^{10}}{\text{Maternal blood volume (estimate)}}$$

Maternal blood volume was estimated on the basis of maternal weight at the time of admission for cesarean section.

Patients were grouped according to amount of fetomaternal hemorrhage detected. In addition, the patients were divided into subgroups by indication for cesarean section to detect any effect of this factor on the incidence of significant fetomaternal hemorrhage.

The χ^2 analysis was performed to compare the rates of significant fetomaternal hemorrhage among subgroups.

Results

A total of 199 patients were available for analysis. Gestational age ranged from 26 to 43 weeks, with 156 patients (78.4%) having attained at least 36 weeks' gestation. Rh status was available in 180 patients. Of these, 156 (86.7%) were Rh positive and 24 (13.3%) were Rh negative.

Cesarean section was performed for the following indications: elective repeat in 23 (11.6%), fetal distress in 62 (31.1%), secondary arrest of labor—cephalopelvic disproportion in 60 (30.2%), breech or other malpresentation in 19 (9.5%), and other indications including placenta previa, abruptio placentae, fetal anomalies, and active herpes simplex virus infection in 32 (16.1%). In three cases (1.5%), the indication for cesarean section was unclear. These patients are included in the "other" group for analysis.

A total of 162 patients (81.4%) had no detectable fetomaternal hemorrhage, 27 (13.6%) had between 1 and 25 ml of fetomaternal hemorrhage; 5 (2.5%) had between 25 and 30 ml, and an additional 5 patients (2.5%) had >30 ml of fetomaternal hemorrhage detected. Clinical characteristics of the patients demonstrating >30 ml of fetal blood in the maternal compartment are shown in Table I.

Table II reveals the degree of fetomaternal hemorrhage by indication for delivery. Rates of significant fetomaternal hemorrhage by subgroup are not statistically different from one another.

Comment

The overall rate of detectable fetomaternal hemorrhage in our study populaton was 37 of 199 or 18.6%. Overall, in 2.5% of our patients there was evidence of a larger fetomaternal hemorrhage than would be neutralized by a single 300 μg dose of Rh immune globulin (i.e., >30 ml).[2] In addition, another 2.5% of patients had between 25 and 30 ml of hemorrhage—a group that may be at borderline risk of sensitization if given a single dose of Rh immune globulin. Ness et al.[8] reported an overall rate of detectable fetomaternal hemorrhage of 12.3% in cesarean section patients, with a rate of 2.8% for hemorrhage in excess of 20 ml.

Population studies have suggested that 0.6% to 1% of patients have significant fetomaternal hemorrhage detected post partum.[8, 9, 11] It remains unclear whether it is cesarean section itself or the antenatal factors predisposing the patient to operative delivery that result in the observed increase in significant fetomaternal hemorrhage. Pilkington[6] found an increased number of fetal cells before delivery in patients who subsequently underwent cesarean delivery, suggesting that the indication for surgery, rather than the procedure

Table II. Breakdown of degree of fetomaternal hemorrhage by indication for cesarean section

*Includes three cases in which indication was unclear.

itself predisposed the patient to an increased fetomaternal hemorrhage.

It is routine practice at our institution to deliver the placenta by manual extraction when performing a cesarean section. Although many groups studying the influence of obstetric factors on the incidence of fetomaternal hemorrhage have found manual removal of the placenta to increase the risk,[3-7] this has generally been studied after vaginal delivery. It is unclear whether this technique used at the time of cesarean section has any independent effect on the rate of fetomaternal hemorrhage over and above that that may be related to the operative delivery itself.

Fetal distress has also been associated in some reports with an increased incidence of significant fetomaternal hemorrhage.[3, 4, 7] In our study, cesarean section for fetal distress was not associated with any increased risk of significant fetomaternal hemorrhage compared with other indications for operative delivery. In fact, comparison of all the groups failed to reveal any significant difference in detectable hemorrhage or large fetomaternal hemorrhage between the various indications for operation.

Although the majority of our patients were Rh positive (86.7%) and therefore not at risk for Rh sensitization, it is unlikely that this factor would alter the amount of fetomaternal hemorrhage occurring at the time of delivery. ABO blood group incompatibility between mother and fetus is known to influence the likelihood of recovering fetal cells in the maternal circulation post partum.[5, 6] We were unable to confirm the ABO types of a sufficient number of our mother-infant pairs to be able to analyze this factor. If there was a delay in obtaining blood samples, ABO incompatibility would decrease the yield of fetal cells on Kleihauer-Betke analysis and therefore lead to an overall underestimation of the degree of hemorrhage. However, the fact that all study specimens were drawn within 4 hours of delivery minimizes any possible confounding effect of this factor.

The patients who demonstrated between 25 and 30 ml of fetal hemorrhage accounted for 2.5% of our study population. Because the error in the technique of quantifying fetal cells can be reasonably assumed to be ± 10%, there are patients in this group who would remain at risk for sensitization if administered only one vial of Rh immune globulin. Although the absolute risk of sensitization in these patients is small, an extra dose of Rh immune globulin would be prudent.

The Kleihauer-Betke acid elution test is a relatively sensitive test for the quantification of fetal bleeding.[12] However, it is labor intensive and even with careful standardization may result in widely varying results. Despite these drawbacks, it is currently the standard test and is used in the majority of clinical institutions and in published reports. New rapid tests for the detection of fetal cells including enzyme-linked antiglobulin tests[13] and a rosetting technique with enzyme-treated indicator erythrocytes[14] have been developed. These could be useful for widespread screening, with the Kleihauer-Betke test available for confirmation.

In 1984, the American College of Obstetricians and Gynecologists issued a recommendation that all Rh-negative women delivered of Rh-positive infants and in a high-risk category be investigated for quantification of fetomaternal hemorrhage post partum.[15] These high-risk categories included abruptio placentae, placenta previa, cesarean delivery, intrauterine manipulation, or manual removal of the placenta. Our study certainly supports the need for postpartum screening in Rh-negative patients undergoing cesarean section, with administration of extra Rh immune globulin to those who demonstrate excessive fetomaternal hemorrhage.

We conclude that in our population of 199 patients undergoing cesarean delivery for all indications, 2.5% had evidence of fetomaternal hemorrhage >30 ml at the time of delivery and an additional 2.5% had between 25 and 30 ml of hemorrhage.

On the basis of these findings, we recommend that all Rh-negative women delivered by cesarean section of Rh-positive infants undergo evaluation for quantification of fetomaternal hemorrhage. This testing should be performed early in the postpartum period to allow

for the administration of the appropriate protective dose of Rh immune globulin.

Prediction of risk for preterm delivery by ultrasonographic measurement of cervical length

H. Frank Andersen, MD, Clark E. Nugent, MD, Suzanne D. Wanty, RN, MSN, and Robert H. Hayashi, MD

Ann Arbor, Michigan

Risk assessment for preterm delivery remains difficult, particularly among women with no prior history of preterm birth. We hypothesized that accurate assessment of cervical length by endovaginal ultrasonography could predict preterm delivery risk. A total of 178 patients with singleton gestations and without cervical incompetence were studied with transabdominal ultrasonography and endovaginal ultrasonographic cervical length measurement and manual vaginal examination of cervical length. A total of 113 patients who were evaluated by 30 weeks' gestation (excluding four induced preterm deliveries) were analyzed. Preterm delivery risk was compared between women with cervical lengths equal to or greater than the median and those with cervical lengths less than the median. An endovaginal ultrasonographic cervical measurement <39 mm was associated with a significantly increased risk of preterm delivery (25.0% versus 6.7%) and detected 76% of preterm births. Manual examination of cervical effacement detected 71% of preterm births, but transabdominal ultrasonographic measurement of cervical length was not preditive. Endovaginal ultrasonographic cervical measurement predicted increased preterm delivery risk regardless of parity or obstetric history. Endovaginal ultrasonography is a promising method for the prediction of risk of preterm birth. Because it has the potential to be an objective measure of cervical length, endovaginal ultrasonography may be superior to manual digital examination for preterm delivery risk assessment. (Am J Obstet Gynecol 1990;163:859-67.)

Key words: Cervix, preterm delivery, endovaginal ultrasonography, transabdominal ultrasonography, risk prediction

Several studies have noted that preterm delivery is more common among women with premature cervical effacement.[1-4] Despite these findings, cervical assessment has not become a routine approach for preterm delivery risk assessment. In part this may be a result of a lack of standardization of methods and difficulty in interpreting results of examinations by different persons.

Ultrasonographic examination has the potential to provide precise, objective, and repeatable measurements of cervical length. With the advent of endovaginal ultrasonography, it is possible to measure cervical length without the confounding effect of bladder filling. In earlier work we showed that endovaginal ultrasonography can provide precise measurements of cervical length.[5] Measurements of cervical length by transabdominal ultrasonography had more scatter throughout gestation than that of endovaginal ultrasonographic measurements. Furthermore, bladder filling improved visualization of the cervix, but artificially lengthened cervical measurements made by transabdominal ultrasonography.[5]

Patients who had cervical evaluation were followed up to delivery to compare risk of preterm birth relative to cervical length measurements made by transabdominal ultrasonography, endovaginal ultrasonography, and manual examination of the cervix. We hypothesized that cervical shortening (effacement) is associated with increased risk of preterm delivery, and that endovaginal ultrasonography measurement of cervical length provides a better estimate of preterm delivery risk than that of other approaches to cervical evaluation.

Methods

Women first seen for routine obstetric ultrasonographic examination from April 1988 through January 1989 were recruited for study. Patients with cervical incompetence or multiple gestation were excluded. Cervical incompetence was determined by history or by physical examination finding of silent cervical dilatation in the early second trimester. Each patient underwent a transabdominal ultrasonographic measure-

ment of cervical length, endovaginal ultrasonographic cervical length measurement (after emptying her bladder), and a manual vaginal examination of the cervix (unless contraindicated by placenta previa or patient refusal). Some patients had more than one scan performed, but only the first scan with complete data was used. All examinations were performed by the same examiner (H. F. A.).

Scans were performed with an Aloka 650 ultrasonography unit (Aloka Co., Ltd., Japan). Transabdominal cervical measurement was performed with a 3.5 MHz curvilinear probe. The cervix was visualized and the distance from internal to external os was measured (Fig. 1). Women were asked not to void for 1 to 2 hours before examination, but a full bladder was not required. Bladder dimensions (vertical and horizontal diameters) were measured and a subjective estimate of bladder filling (empty, partial, full) was recorded.

After the patient emptied her bladder, endovaginal probe cervical measurement was made with a 5 MHz vaginal probe attached to the Aloka 650 unit. The internal cervical os was visualized in the sagittal plane and the probe was manipulated until the entire cervical canal could be visualized. Markers were placed at the furthest points at which the cervical canal walls were juxtaposed and the cervical length was measured (Figs. 2 and 3). In some cases the cervix was too long to be entirely visualized in one scan. In these instances, a suitable structure such as a mucous cyst was used as a reference point and measurements were made from the internal os and the external os to the reference point and then added. Ultrasonographic measurements were performed twice by each method and the mean of the two measurements was used for each method.

After the ultrasonographic examination, manual examination was performed by estimating the length from the external cervical os to the cervical-uterine junction, as palpated through the vaginal fornix. The cervical canal was not probed by the examining finger.

Cervical length data were not reported to the patient's obstetric care provider. Informed consent was obtained for this study, which was approved by the institutional review board.

After delivery, charts were reviewed for pregnancy outcome, age, and obstetric index (number of prior term deliveries, preterm deliveries, and abortions). Estimated date of confinement was determined by the best obstetric estimate, which included menstrual data, clinical evaluation, and ultrasonographic examination. The

estimated date of confinement was used to determine estimated gestational age at the time of cervical measurement and at delivery. Preterm delivery was defined as delivery before 37 completed weeks' gestation (259 days).

Because of progressive shortening of average cervical length after 30 weeks' gestation, statistical evaluation was restricted to patients examined by 30 completed weeks' estimated gestational age. Data were analyzed with a standard microcomputer statistical package.[6] Statistical comparisons were made with the Student t test for comparisons of mean cervical length and χ^2 analysis of risk of preterm delivery. A p value <0.05 was used to reject the null hypothesis of no difference.

Results

A total of 178 women with singleton gestations and without cervical incompetence were evaluated. Ten patients were lost to follow-up (three first-trimester abortion, seven delivered elsewhere). Four patients had induced preterm delivery (indications: Rh isoimmunization, severe intrauterine growth retardation, and preeclampsia) and were excluded from evaluation. Figs. 4, 5, and 6 present graphs of measurements by the three methods throughout gestation. By all three methods there appears to be progressive shortening of average cervical length after 30 weeks' gestation. Horizontal dashed lines represent the median (50th percentile) for cervical length measurements by 30 weeks' estimated gestational age. Visual analysis suggests that the majority of preterm deliveries occurred in patients with endovaginal ultrasonographic or manual examination cervical measurements below the median; however, preterm patients are evenly scattered above and below the median for abdominal ultrasonographic measurements.

A total of 113 patients had cervical length measurements made by 30 weeks' gestation. Norms for cervical length through 30 weeks' gestation are shown in Table I. Abdominal ultrasonographic cervical measurement

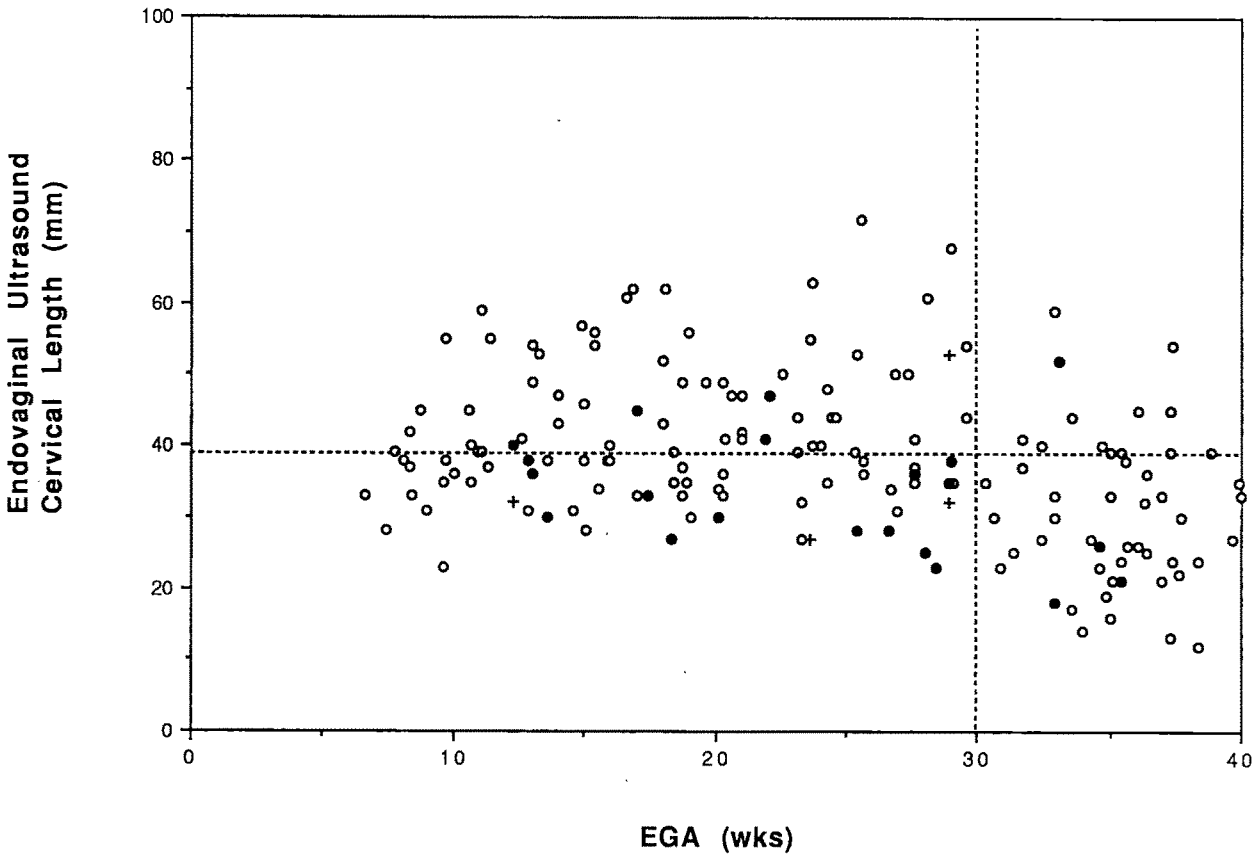

Fig. 5. Scattergram of endovaginal ultrasonographic measurements of cervix throughout gestation. *Open circles,* term delivery; *filled circles,* spontaneous preterm delivery; +, induced preterm delivery. *Horizontal dashed line* represents median cervical length for measurements made by 30 weeks' estimated gestational age *(vertical dashed line).*

was not possible in 6.2% of patients because of poor visualization of the cervix as a result of incomplete bladder filling. In one patient endovaginal ultrasonographic measurement was not possible because of severe constipation.

Comparison of mean cervical length of patients who were delivered of infants preterm and at term is presented in Table II. By each method mean cervical length was shorter among patients who were delivered preterm, but only measurements made with endovaginal ultrasonography or manual examination were statistically significant.

Sensitivity, specificity, and predictive values were determined for each method with cutoff values that represented the 50th and 25th percentiles for the range of measurements found through 30 weeks' gestation. The data are presented in Table III. The relative risk of preterm delivery in women with cervical shortening below the 50th percentile was 3.7 compared with that of women with cervical length longer than the 50th percentile. Cervical shortening below the 50th percentile by manual examination resulted in a 2.9-fold increased risk of preterm delivery. Cervical shortening measured by transabdominal ultrasonography was not statistically significantly related to preterm delivery risk, although shortening below the 25th percentile did result in a nearly twofold increased risk of preterm delivery.

Logistic regression analysis of risk of preterm delivery by cervical length measured by endovaginal ultrasonography showed a progressive and statistically significant trend toward higher risk of preterm birth with shorter cervical length (Fig. 7). Endovaginal ultrasonographic cervical assessment was compared in nulliparous women, multiparous women without prior preterm delivery, and multiparous women with a history of preterm delivery (Table IV). The overall results were statistically significant, although individual categories of obstetric history contained too few numbers to reach significance separately.

Comment

Risk assessment for preterm delivery continues to be a difficult problem in obstetrics. Numerous investigators have developed or modified risk scoring systems for preterm birth, but results have been variable.[7-10] Not infrequently, promising results by one investigator are not confirmed by others with the same system.[11,12] However, most risk assessment studies have noted that premature cervical effacement is associated with an increased risk of preterm delivery.

Independent studies of cervical effacement and dilatation have confirmed the association with preterm delivery.[1-4] This contrasts with older studies that suggested that cervical effacement and dilatation is a common occurrence as pregnancy progresses.[13-15] These earlier studies tend to frustrate cervical assessment in women at risk for preterm labor because some clinicians believe that cervical change is a normal phenomenon. Furthermore, differences among individual examiners makes standardization of findings difficult.

Ultrasonography and particularly endovaginal ultrasonography has the potential to provide objective, repeatable cervical length measurements. The vaginal scanning approach has several advantages over the

transabdominal method for evaluation of the cervix. With an empty bladder about half of cervical length measurements are not possible because of inadequate visualiztion of the cervix, but bladder filling significantly lengthens the measured cervical length.[5, 16, 17] Endovaginal scanning with an empty bladder removes a major confounding factor in the assessment of cervical length and visualization of the cervix is possible in nearly all patients. It is interesting that mean cervical lengths determined by endovaginal ultrasonography are similar to those found by Zemlyn, Varma, and Bowie[18-20] in studies that evaluated the cervix by transabdominal ultrasonography with an empty or nearly empty bladder.

Although several studies of ultrasonographic cervical evaluation have concentrated on demonstration of cervical incompetence, the principal ultrasonographic indication of cervical incompetence is dilatation of the endocervical canal with prolapse of amniotic membranes.[21-23] Two investigators have suggested that cervical shortening is indicative of cervical incompetence.[24, 25] These authors excluded women whose pregnancies ultimately resulted in preterm birth; therefore, their findings cannot be directly compared with ours. In an earlier study of a small group of women with clinically demonstrated incompetent cervix, we failed to find a significant difference in cervical length.[5]

Our results confirm that premature cervical effacement is associated with an increased risk of preterm delivery. More specifically, risk of preterm delivery is inversely proportional to cervical length and increases significantly with shorter cervical length measurements. It appears that risk detection by cervical length measurement works well in nulliparous women and women without prior preterm deliveries, groups that have been difficult to adequately assess for risk of preterm delivery. In this study endovaginal ultrasonographic measurement was clearly superior to transabdominal ultrasonographic measurement in the prediction of preterm delivery risk. It is important to note that this study was cross-sectional, that is, each patient was included only once. That makes our data applicable for screening a

<39 mm	12.5% (24)	25.0% (16)	50.0% (12)

$p = 0.015$ (Mantel-Haenszel χ^2). *VAGCX,* Endovaginal ultrasonographic cervical length measurement. Number of patients in parentheses.

population of pregnant women; but these data do not answer the question of the significance of change in the cervical examination.

Manual examination also showed a significant association between cervical shortening and preterm delivery risk. Cervical dilatation was not evaluated in this study because we prefer to avoid probing the cervical canal to the level of the internal os. All examinations were performed by a single examiner after the ultrasonographic examination, raising the possibility of bias in the measurement. Furthermore, the comparability of cervical examinations among multiple examiners was not tested. Further study is needed to better quantify the value of manual cervical examination.

The mechanism of cervical effacement is not well understood, but involves a complex biochemical and structural reorganization of the connective tissue of the cervix. Although the nature of the relationship between myometrial contractions and cervical effacement is not known, it is clear to the clinician that contractions and

cervical change are closely linked. Recent work by Main, et al.[26] has suggested that increased uterine contractions detected during routine monitoring at prenatal visits detects patients at increased risk of preterm delivery. That finding, coupled with our work, suggests that physiologic indicators of preterm labor may be identifiable and useful in risk assessment.

This study shows a relationship between cervical shortening and preterm delivery risk. We cannot recommend an optimum cutoff point for cervical length to predict preterm delivery risk. It is important to note that this study needs to be validated by further investigations involving multiple examiners and other populations. In addition, more study is needed to evaluate the cervix in a longitudinal fashion throughout pregnancy, and to examine the combination of two or more examination modalities as predictors of preterm delivery.

Is indicated or spontaneous preterm delivery more advantageous for the fetus?

John Owen, MD, Susan L. Baker, MD, John C. Hauth, MD, Robert L. Goldenberg, MD, Richard O. Davis, M.D., and Rachel L. Copper, MSN
Birmingham, Alabama

We performed a case-control study to determine whether fetuses delivered prematurely because of pregnancy complications (primarily pregnancy-associated hypertensive disease) had a different neonatal course than that of those born after either spontaneous preterm labor or after premature rupture of the membranes. Two case-control populations were matched by gestational age at delivery, fetal sex, and race. There was no perinatal survival advantage in babies delivered from "stressed" pregnancies. Selected neonatal morbidities were generally similar, but there was an increased incidence of necrotizing enterocolitis in babies born after preterm labor and a higher incidence of both necrotizing enterocolitis and neonatal sepsis after premature rupture of the membranes. We conclude that a "stressed" pregnancy confers a negligible survival advantage to the fetus (AM J OBSTET GYNECOL 1990;163:868-72.)

Key words: Perinatal survival, fetal lung maturation, preterm labor, complicated pregnancy

Numerous studies support a relationship between pregnancy complications and accelerated fetal pulmonary maturation.[1] One explanation for this phenomenon is that the fetus responds to a "stressed" environment by increasing its adrenal glucocorticoid production. This leads to earlier production of surface active phospholipids in the fetal lungs.[6] Whereas the laboratory evidence of accelerated pulmonary maturation in certain complicated pregnancies (especially pregnancy-associated hypertensive diseases) is compelling, not all authors agree.[7-9] This disagreement may be a result of differences in the biochemical markers used to define the accelerated maturation, differences in the definition of "stressed pregnancies," and possibly the control patients used for comparison. Nevertheless the implication is that babies delivered prematurely from complicated pregnancies have a survival advantage compared with their counterparts delivered as a result of spontaneous, idiopathic preterm labor. We could find little data to support this common clinical assumption.[10]

Because respiratory distress syndrome and its sequelae are the leading causes of neonatal mortality in the United States,[11] it seems plausible that any factor, such as "intrauterine stress," that may decrease the incidence of hyaline membrane disease would improve the neonatal course. We therefore performed a case-control study by comparing neonates whose mothers had an indicated preterm birth for maternal or fetal indications with two control populations. The first of these included neonates who were delivered as a result of spontaneous preterm labor with no prior membrane rupture, whereas the other group comprised neonates delivered prematurely after premature rupture of the membranes.

Methods

Data were collected prospectively as part of a multicenter trial of preterm birth prevention funded by the March of Dimes at the University of Alabama Hospitals. During the study period from November, 1982, through April, 1986, all cases of preterm delivery between 20 and 36 weeks' gestation were identified by specially trained research nurses. Each maternal and neonatal record was then reviewed for specific information about the pregnancy, labor, delivery, and neonatal course. The data were collected onto standardized coding sheets and entered into a central computerized data base. The information recorded included demographic characteristics, underlying maternal disease states, use of tocolytic therapy or glucocorticoids, delivery method, and the specific reason for the preterm birth. The neonatal charts were abstracted for the presence of specified complications contained in the final discharge diagnoses approved by the responsible neonatologist. Infant ventilation time was coded in whole number of days, and one day was considered to be at least 12 hours. The presence and type of any recognized congenital anomalies were also recorded.

Both obstetric and neonatal gestational dating cri-

teria were reviewed by one of the principal investigators. Sonographic data are routinely obtained as part of our general obstetric care, and most of our study population had an early ultrasonographic examination to confirm our clinical gestational dating criteria.

Only those women who were delivered of a live-born infant between 24 and 36 weeks' gestation were included in the analysis. We defined a live-born infant as any baby who had a nonzero Apgar score at either 1 or 5 minutes. A perinatal death was defined as the death of a live-born infant before discharge from the hospital. Neonatal days in the hospital were counted from the day of birth until the baby was either discharged home or transferred to another facility.

The diagnosis of membrane rupture was usually made by the observation of vaginal pooling of amniotic fluid, which, after drying, showed the typical ferning pattern. The use and choice of tocolytic agents for patients with preterm labor were determined by the attending physician. Currently, premature membrane rupture is considered a contraindication to tocolytic therapy at our institution. However, during the term of this study, patients with ruptured membranes often received a brief (≤24-hour) course of parenteral magnesium sulfate. Each decision to effect an indicated preterm birth was made by the attending physician.

During this study period 1183 women were delivered of singleton, live-born infants between 24 and 36 weeks[3] gestation. None of these women had received antenatal glucocorticoid therapy. Furthermore, we excluded women whose newborn had a major organ system anomaly and women with rhesus isoimmunization, insulin-dependent diabetes mellitus, homozygous hemoglobinopathies, or sepsis. Application of these criteria yielded a population of 1015 gravidas. Of these, 202 women had an indicated preterm delivery, 537 were delivered after spontaneous preterm labor, and 276 were delivered after premature rupture of the membranes (PROM). A total of 178 women with an indicated preterm delivery were matched to women with a spontaneous preterm delivery on the basis of gestational age in completed weeks, maternal race, and fetal sex. In like manner, 159 women with an indicated preterm delivery were able to be matched to a group of women with preterm membrane rupture and delivery. Women with an indicated preterm delivery who were matched with those with preterm labor were, by design, not identical to those with an indicated preterm delivery who were matched with a group of women with PROM. Therefore, separate analyses were performed on the two match-paired, case-control groups.

Data were analyzed with the SAS (Statistical Analysis System, Carey, N.C.) software release 6.01 for personal computers. The Student t test, the χ^2 test of proportions, the Fisher exact test, and the Wilcoxon rank-sum test for nonparametric data were used where appropriate.

Table I. Indications for preterm delivery

Indications	*Indicated preterm delivery versus preterm labor (N = 178)*		*Indicated preterm delivery versus PROM (N = 159)*

IPD, Indicated preterm delivery; *PTL,* preterm labor.
*Abnormal antepartum testing, oligohydramnios, suspected growth retardation.

Results

The primary delivery indications for the two populations with indicated preterm delivery are listed in Table I. In some cases more than one indication was present. When this occurred, the indication considered to be the proximate cause of the delivery was chosen; we did not analyze these patients separately. The two populations with indicated preterm delivery populations were similar but not identical, and the majority of indicated preterm births were for maternal hypertensive conditions.

Selected population characteristics for the indicated preterm delivery versus preterm labor and indicated preterm delivery versus PROM groups are shown in Tables II and III. Because of the matching criteria, the mean gestational ages and proportions of nonwhite gravidas were identical. However, the patients with indicated preterm delivery were significantly older and contained a higher proportion of nulliparous patients. In addition, women in the preterm labor and PROM control groups were more likely to have labored, to have undergone a vaginal delivery, and to have received parenteral tocolytic agents during their pregnancy. Small proportions of the patients with indicated preterm delivery (13 of 159 and 15 of 178) received tocolytic agents. Most of these women were first seen with vaginal bleeding and preterm contractions. These patients received a brief course of parenteral tocolytic therapy during initial evaluation until the clinical diagnosis of abruptio placenta or placenta previa was con-

firmed or mandated delivery. The remaining patients had received a course of tocolytic therapy before they were seen for an indicated delivery.

The babies with indicated preterm delivery were smaller and were more likely to be under the 10th percentile for birth weight according to the criteria of Brenner et al.[12] Selected neonatal outcomes are shown in Tables IV and V for the indicated preterm delivery versus preterm labor and indicated preterm delivery versus PROM matched groups of patients. Most importantly, the perinatal mortalities and the incidence of the respiratory distress syndrome were similar between the group with indicated preterm delivery and their respective control populations. In most other respects, the case and control neonates were not significantly different. However, the incidence of necrotizing enterocolitis was higher in both control groups, whereas the neonates delivered because of maternal PROM had significantly more neonatal sepsis. The neonates with indicated preterm delivery also had longer hospital stays (Wilcoxon rank-sum test), whereas the indicated preterm delivery and preterm labor neonates had a significantly higher incidence of hyperbilirubinemia.

Comment

This is the first case-control study of which we are aware that assesses the risk of neonatal mortality and selected morbidities resultant from an indicated preterm birth compared with those after spontaneous preterm labor or PROM. There was no survival advantage for infants delivered from the selected complicated pregnancies. The neonatal morbidity rates were also similar. However, both control groups had significantly more necrotizing enterocolitis and the PROM group had significantly more neonatal sepsis than that of their matched populations with indicated preterm delivery. The relationship between neonatal infectious morbidity and PROM has been clearly established.[13] Similarly, necrotizing enterocolitis may be partly a result of underlying infectious agents, and one might anticipate its occurrence more often after PROM. That it should occur more frequently after preterm labor with intact membranes is more obscure unless one considers that a sizable number of preterm labors are caused by subclinical infections or that the group with indicated preterm delivery had a fourfold greater incidence of cesarean deliveries. The stress of labor and contact with the genital flora may have been contributing factors. Compared with both control populations, the neonates in the group with indicated preterm delivery also required significantly more days in the hospital. This likely was related either to their smaller birth weights, inasmuch as discharge criteria usually demanded a weight of at least 2000 gm, or to their indicated maternal transport from remote locations.

Table IV. Neonatal outcome, indicated preterm delivery versus preterm labor ($N = 178$)

IPD, Indicated preterm delivery.

Whereas the patients with indicated preterm delivery and their control populations were matched by gestational age, race,[14] and fetal sex,[11] they were in some respects dissimilar. Although antenatal glucocorticoid therapy has been shown in most reports to decrease the incidence and severity of hyaline membrane disease with intact membranes, the relationship between glucocorticoid administration and respiratory distress syndrome in cases of PROM is more controversial.[15] Therefore, we did not include patients who had received betamethasone. In addition, we excluded from the control groups any women who had recognized maternal or fetal pathology that could have acted as an additional stress. Finally, we omitted from the populations with indicated preterm delivery any complications such as maternal diabetes mellitus or isoimmunization because of the controversies surrounding their effects on fetal lung maturation.[16]

Other possible sources of bias included the presence of labor,[4] delivery route,[17,18] and use of tocolytic agents.[19] Our data show that women first seen with spontaneous preterm labor and PROM are more likely to have a vaginal delivery than are those who have an indication for a preterm delivery. Because the risk of the development of respiratory distress syndrome may be significantly influenced by these factors,[16] they may have, in part, accounted for the similar neonatal outcomes. We also considered that our population with indicated preterm delivery may not have been sufficiently "stressed" or that delivery was effected before the beneficial effect of the intrauterine stress was complete. Because the mechanism and timing of this process are poorly characterized, it is possible that our collection of complicated pregnancies might not have contained enough severely stressed fetuses to show a difference. Gestational age may also be a factor in the development of accelerated pulmonary maturation, being more pronounced in certain gestational age ranges.[10] However, examination of the pregnancy outcomes on either side of 32 weeks' gestation showed similar results. The Apgar scores did not indicate that the neonates with indicated preterm delivery had an increased incidence of intrapartum asphyxia, although this possibility was not entirely excluded. The relationship between fetal hypoxemia and complications of pregnancy are well described, and asphyxia may predispose neonates to the development of respiratory distress syndrome.[20] This could negate the beneficial effects of any previous chronic fetal stress.

We conclude that the fetal stress of pregnancy complications severe enough to warrant an indicated premature birth do not confer a neonatal survival advantage compared with babies whose mothers were delivered because of PROM or preterm labor. It is most likely that PROM and preterm labor themselves act to stress the fetus.

Evaluation of a risk scoring system as a predictor of preterm birth in an indigent population

John Owen, MD, Robert L. Goldenberg, MD, Richard O. Davis, MD, Katharine A. Kirk, PhD, and Rachel L. Copper, MSN
Birmingham, Alabama

A risk scoring system designed to predict spontaneous preterm birth was implemented in a large, indigent population as part of a multicenter trial of preterm birth prevention. A total of 7478 women with singleton gestations were screened and followed up prospectively at the Birmingham project center. Patients who had an indicated preterm delivery or a fetal anomaly were excluded from the study population. Analysis by assigned risk score and parity showed that, whereas the sensitivity and positive predictive value were better in multiparous women than in nulliparous women, overall the values were low. Logistic regression analyses of the multiparous and nulliparous populations showed independent sets of significant ($p \leq 0.05$) risk variables. A history of preterm delivery and a low prepregnancy weight were the most predictive risk factors in the multiparous and nulliparous models, respectively. We conclude that the clinical usefulness of a risk scoring system to predict spontaneous preterm birth in an indigent population is limited.
(AM J OBSTET GYNECOL 1990;163:873-9.)

Key words: Preterm birth, risk scoring system, premature labor

Preterm birth is one of the most significant health problems in the United States.[1] Neonatal management of low birth weight–infants has improved: methods to prevent premature birth have not. The causes of prematurity are complex, poorly understood, and remain under intensive investigation. In some cases, underlying maternal diseases, known to increase the likelihood of maternal or fetal compromise, may be recognized and treated early in pregnancy. Other conditions, such as preeclampsia, are often treated by preterm delivery. Whereas a portion of preterm deliveries are indicated for maternal or fetal conditions, the majority come after preterm labor with or without antecedent rupture of the membranes.

Previous authors[2-6] have sought to identify patients at high risk of preterm labor in an attempt to alter its natural history. Because many patients with preterm labor are seen too late for successful tocolytic therapy, the concept of early recognition of the signs and symptoms of preterm labor has been stressed. Central to these efforts has been a risk scoring system that comprises various factors that have a statistically significant relationship to preterm delivery.[7] One system devised by Papiernik has been popularized in this country by Creasy and others.[8] This system depends on the identification of individually weighted risk factors. The individual risk values are then tallied to produce a combined risk score and distinguishes low-risk from high-risk groups. Patients considered to be at high risk are given special attention during their antenatal course. This consists of education about the symptoms of preterm labor, frequent prenatal visits, and assessment of the signs of preterm labor (e.g., cervical dilatation). Stress reduction and correction of identified risk factors (e.g., cigarette smoking) has commonly been included in these programs.

To understand the potential usefulness of a risk scoring system, it should be viewed within the entire context of the preterm birth dilemma, the primary goal of which should be the prevention of neonatal morbidity and mortality (Fig. 1). Unless universal changes in prenatal care are adopted in an attempt to decrease the incidence of all preterm births, specific modifications to routine prenatal care depend on the accurate identification of those women who are at the highest risk of preterm labor. Therefore, to be clinically useful, a risk scoring system should have a high sensitivity, and to be cost effective, it should have a high positive predictive value. This study examines the clinical usefulness of a risk scoring system for the prediction of spontaneous preterm birth in a large, indigent population. Because many of the risk variables were applicable only to multiparous patients, we sought to confirm, as others

have shown,[3, 4] that the scoring system would have different predictive values in nulliparous versus multiparous patients.

Methods

As part of a multicenter trial of preterm labor prevention, women who registered in the Jefferson County Health Department system for obstetric care and who had an estimated date of confinement between August 15, 1983 and April 19, 1986 were screened for risk factors in accordance with a risk scoring system (Table I). However, patients at >30 weeks' gestation at the first visit were excluded. The initial evaluation and risk score assessment included 35 risk variables and was performed as soon as possible after the first prenatal visit. Women who were first seen for care before 22 weeks' gestation were reevaluated between 22 and 26 weeks and their scores were adjusted accordingly. Patients with total scores <10 were considered to be at low risk and were given the usual prenatal care. Routine prenatal care included screening for pregnancy complications and referral to our high-risk obstetric clinic when appropriate. Patients with scores ≥10 were offered entry into the prospective preterm birth prevention program staffed by specially trained nurse practitioners. The program stressed early patient and physician recognition of preterm labor, immediate evaluation of patients suspected to have preterm labor, and appropriate tocolytic therapy. Patients who agreed to participate were randomly assigned to either the intervention group or to a control group of women who received routine prenatal care. Patients who refused to participate or who were ineligible (e.g., inability to contact the patient in time for randomization) also received routine prenatal care. Patients who underwent the initial screening and risk assessment were followed up prospectively. Data were collected and recorded on standardized coding sheets by trained research personnel. These were entered into a central computerized data base. Although this data base contained information from each of the five project centers, for this report we chose to include only the project data on singleton pregnancies from our center (the Birmingham center). Our center entered and delivered nearly 40% of the clinical participants, thus, the uniform prenatal care within a single institution would improve the comparability of patient data with respect to management strategies. At our institution there was no significant difference in the incidence of preterm delivery between the intervention group and the control patients.[9] Therefore the intervention group was included in the analysis of the scoring system. Patients who had an indicated preterm delivery or a significant fetal anomaly were excluded from the analyses.

Table I. Risk scoring system

Individual risk variable scores					
1	*2*	*3*	*4*	*5*	*10*
Historic factors					
First-trimester losses = 1	Chronic hypertension	Height <152 cm	Age ≤17 yr	Second-trimester losses = 1	Each prior PTB*
Education 9-11th grade	Marital status single	Prepregnancy weight <45.5 kg	Pyelonephritis	Cone biopsy*	Each prior pregnancy with PTL and term birth*
Last birth <1 year*	First-trimester losses = 2	First-trimester losses >2		Uterine anomaly†	Second-trimester losses ≥2
	Education ≤8 grade			DES exposure†	
Factors associated with this pregnancy					
Preschool children at home*	Bacteriuria	Uterine fibroids	Bleeding after 12 wk	Oligohydramnios†	Multiple gestation†
Work outside of home	Poor weight gain	Febrile illness	Cervical length <1 cm†	Polyhydramnios†	Abdominal or cervical surgery†
	Age 18-19 yr or >40 yr	Weight loss	Internal os dilated*	Placenta previa†	
	Heavy work	Long commute†	Uterine irritability†		
	Proteinuria ≥1+	Presenting part engaged at 32 weeks†			
	Smokes >10 cigarettes/day				

PTL, Preterm labor; *PTB,* preterm birth; *DES,* diethylstilbestrol.
*Excluded from logistic regression analysis in nulliparas only (see Methods section).
†Excluded from logistic regression analysis in all patients (see Methods section).

Because the definition of preterm birth depends on accurate pregnancy dating, both obstetric and neonatal criteria were collected. The records of all patients who were delivered of infants before 37 completed weeks' gestation, in whom there was greater than a 2-week discrepancy between the obstetric and neonatal gestational age estimates, and who had babies weighing under 2750 gm were reviewed by one of the principal investigators before a final gestational age assignment was made. Because of the intake scheduling, most of our patients had an early ultrasonographic examination.[10] We defined delivery before 37 completed weeks' gestation as a preterm birth and delivery before 32 completed weeks' gestation as a very preterm birth.

Patients who met established criteria for preterm labor during their pregnancy were usually treated with parenteral magnesium sulfate or ritodrine hydrochloride at the discretion of the attending physician. Most women who received parenteral tocolytic therapy were also given oral β-sympathomimetic therapy after the intravenous medications were stopped. In the absence of contraindications, most of the patients in preterm labor received a course of tocolytic therapy. At our institution women are not prescribed parenteral tocolytic therapy after 35 completed weeks' gestation. Labor and delivery management decisions were made by the resident staff and attending physicians.

Data were analyzed with the SAS (Statistical Analysis System, Carey, N.C.) software release 6.03 for personal computers and release 5.18 for the IBM 3270 mainframe. The χ^2 test of proportions was used where appropriate, and stepwise, multiple logistic regression was performed with the Logist procedure.[11]

Results

Of the 7952 gravidas with singleton gestations, 244 (3.1%) were excluded because they had an indicated preterm delivery. These patients represented 27% of

- Identification of the pregnancy at risk for preterm labor
  - Risk scoring system
- Interventions to recognize the early prodrome of and prevent the occurrence of preterm labor
  - Antenatal evaluation and education
  - Bed rest
- Interventions to treat preterm labor
  - Tocolytic therapy
- Interventions to decrease the morbidity associated with preterm birth
  - Transfer to level III center
  - Infection surveillance and treatment
  - Agents to accelerate lung maturation
  - Labor and delivery management
- Neonatal interventions to minimize the sequelae of preterm birth
  - Level III nursery

PTB, Preterm birth (<37 weeks); *VPTB*, very preterm birth (<32 weeks).

the entire preterm birth population. In addition, 230 (2.9%) were excluded because of a fetal or neonatal anomaly. Of the remaining 7478 women, 3439 (46%) were nulliparous and 4039 (54%) were multiparous. Of this study group of 7478 women, 85% were assigned a low-risk score, and 15% were assigned a high-risk score. Of the multiparous women 19% received a high-risk score, whereas only 10% of the nulliparous women had a score ≥10. The racial composition of the study group was 28% white and 72% nonwhite; the mean age was 22 ± 5 years (range, 11 to 46).

The incidence of preterm birth and very preterm birth according to risk group is shown in Table II. Fig. 2 depicts the incidence of preterm birth and very preterm birth by risk score partitions and parity groups. Whereas the likelihood of a multiparous patient being delivered of a premature infant increased with advancing score group, the number of patients who attained high scores was small. Conversely, the relationship between score group and preterm delivery in the nulliparous population was not as pronounced, and only two patients attained scores ≥20; neither had a preterm birth.

Summary predictive values are shown in Tables III and IV and reflect comparisons between the high- and low-risk groups. The positive and negative predictive values were determined from the observed incidences of preterm birth and very preterm birth in our population. Whereas the overall sensitivity and positive predictive values of the scoring system were poor, the multiparous group had considerably higher values than those of the nulliparous group. The negative predictive values and specificities, as others[12] have shown, were good.

The results of the multiple logistic regression analyses are shown in Table V. Of the risk variables that were entered into the algorithm (18 for the nulliparous group and 24 for the multiparous group), few were selected as significant contributors to either a preterm birth or a very preterm birth. Note that several risk factors were excluded from the logistic models because of an insufficient number of nonzero values (Table I). A history of preterm delivery was the most significant factor identified in the multiparous group, and a low prepregnancy weight was the best predictor in the nulliparous patients. Moreover, there was little overlap in risk factors between the nulliparous and multiparous populations. For each of the significant risk factors, the logistic regression analyses confirmed the relationship between a higher risk score value and the chance of preterm birth and very preterm birth.

Although ethnic background was not one of the risk variables in the scoring system, other authors[3] have reported that black women have an increased risk of spontaneous preterm delivery compared with white women. To evaluate race as an independent risk factor we performed the logistic regression as above but included a variable designated as "white" or "nonwhite." Race did not emerge as a significant independent risk factor for either preterm birth or very preterm birth ($p > 0.05$).

Comment

In this study we analyzed data collected as part of the multicenter trial of preterm birth prevention funded by the March of Dimes, and the study represents the center that entered the largest number of patients into the clinical trial. The results of the intervention program were disappointing.[9] Therefore analysis of each of the variables used in the risk scoring system is indicated. Our results show that even with the

carefully controlled application of a scoring system based on a combination of historic and pregnancy-related events in a large population, the sensitivity and positive predictive values of the risk assignments were poor. Moreover, its use in nulliparous women was limited even further because of the effects of parity on the predictive values. We believe that this is primarily a result of the influence of a prior preterm birth on future reproductive performance. By definition, nulliparous women lack the single most predictive risk factor in the scoring system. Although the clinical usefulness of a risk scoring system has been confirmed in some populations,[5, 6, 8] other reports have not been confirmatory. Main[12] has summarized the results of seven studies that dealt with preterm birth prevention and reported generally poor sensitivities and positive predictive values.

Screening tests should have a high sensitivity to allow treatment of the most patients at risk. If the intervention were either costly or carried a significant risk to the patient, then a high positive predictive value would also be necessary. In this case the treatment, a formal program of prematurity prevention, appears to have few significant ill effects.[9] Conversely, such a program is costly for the system and perhaps to the individual patient (frequent visits), but this has not been fully evaluated.

As with others,[3] we excluded patients who underwent an indicated preterm birth because to include these patients might have made an unrealistic demand on a scoring system that was devised to predict spontaneous preterm birth. Conversely, certain factors such as chronic hypertension, extremes of maternal age, and cigarette smoking could be related to the development of pregnancy complications severe enough to prompt a preterm delivery. A possible explanation for this postulate is that the protocol of preterm birth prevention was not designed to treat this type of patient. To answer this question, one could include this group of patients in the analysis.

The decision to include only patients with a singleton gestation may have influenced our results inasmuch as the relationship between multiple gestation and preterm labor is well established. But, given the other well-recognized obstetric complications of a multiple gestation, we thought that the use of a scoring system to identify these patients was of little clinical value. Finally, we excluded patients who had an anomalous fetus. We could identify no risk factors, save advanced maternal age, that could have predicted this type of adverse pregnancy outcome and believe that this removed a possible source of bias from the analysis.

Multiple logistic regression analyses of the multiparous and nulliparous groups at both pre-32 and pre-37 week end points showed different sets of significant risk factors. The reason for this disparity is unclear. Although the nulliparous model was allowed six fewer risk variables by design, the multiparous model contained all the risk variables that had a sufficient number of nonzero values. Of these only a low prepregnancy weight and a history of preterm birth were significant at both gestational age end points for the nulliparous and multiparous patients, respectively. Other authors[3] initially used a univariate analysis to identify significant risk variables for inclusion in a logistic regression model. A univariate procedure that screens for variables used in a multiple logistic regression analysis may be blind to the interaction patterns among the parameters of interest. Therefore we performed the entire analysis with multiple logistic regression with a stepwise, backward elimination procedure. This method permitted the multivariate analysis of each variable adjusted for the others present in the model and ultimately selected risk factors that made a significant ($p \leq 0.05$) contribution to the prediction of spontaneous premature delivery.

Because the usefulness of a risk scoring system has been shown in other populations, we considered why it had such a poor positive predictive value in our patients. From a socioeconomic standpoint our patients were relatively homogeneous and represented an underprivileged group. Therefore risk variables chosen to stratify patients by their economic class, acknowl-

Table III. Summary predictive values for delivery <37 weeks

	Sensitivity	*Specificity*	*PV+*	*PV−*

Table V. Significant risk variables from logistic regression analysis

	Nulliparous patients		*Multiparous patients*	
Delivery before	*Variable*	*p Value*	*Variable*	*p Value*
37 weeks	Low prepregnancy weight	0.006	Prior preterm delivery	<0.001
	Poor weight gain	0.04	Prior cone biopsy	<0.001
	Education	0.04	Bleeding after 12 wk	<0.001
	Employment status	0.04	Maternal age	<0.001
			Marital status	0.02
32 weeks	Low prepregnancy weight	0.03	Prior preterm delivery	<0.001
			Cervix dilated at 22 wk	0.01
			Second-trimester losses	0.05
			First-trimester losses	0.01

edging the contribution of socioeconomic factors to preterm birth, would have been extraneous. Another consideration was the validity of historic data used in the scoring system. A negative response to questions about the presence of a uterine anomaly or in utero exposure to diethylstilbestrol must be viewed as problematic, because this information may not have been reliably ascertained in our population. Other factors, such as amniotic fluid volume disorders, depend on serial ultrasonographic information that may not have been obtained. Because our study participants were not blinded to the status of their risk group, it is conceivable that this knowledge somehow influenced the natural history of preterm birth. This possibility cannot be excluded without further research. A similar concept might also be applicable to our inclusion of the intervention group patients, despite the fact that no difference in the preterm birth rate was observed. Finally we considered that the content of our routine prenatal care and our use of tocolytic agents may have altered or masked the predictive values inherent in the risk scoring system. Nevertheless, despite its poor sensitivity and positive predictive value, the risk scoring system does identify a group of patients at significantly increased risk of preterm delivery. In the multiparous population, high-risk patients had nearly three times the incidence of preterm birth and four times the incidence of very preterm birth compared with low-risk patients.

We concur with Iams[13] that current risk scoring systems are flawed by a lack of information about the specific pathophysiologic events that initiate premature labor. On the other hand, can the knowledge gained by the study of these risk factors contribute to this critical area of research? Most important, can the use of a preterm birth prevention risk scoring system make a manifest contribution to prenatal care? Certainly the identification and correction of such factors as poor weight gain are desirable. Despite these possibilities, the clinical usefulness of this risk scoring system appears to be limited, and its dissemination into obstetric practice should await further proof of its efficacy.

A prospective randomized comparison of oral terbutaline and magnesium oxide for the maintenance of tocolysis

Louis E. Ridgway III, MD, Kevin Muise, MD, Jeffrey W. Wright, MD, Robert M. Patterson, MD,* and Edward R. Newton, MD
San Antonio, Texas

We compared oral magnesium oxide with oral terbutaline sulfate in a prospective, randomized manner to determine efficacy and side effects. Preterm labor patients whose labor was arrested with parenteral tocolysis were randomized to oral tocolysis with either magnesium oxide, 200 mg every 3 to 4 hours ($n = 23$), or terbutaline, 2.5 to 5 mg every 3 to 4 hours ($n = 27$). The number of patients who were delivered of infants before 36 weeks' gestation was similar between groups (18.5% receiving terbutaline versus 17.4% receiving magnesium). At least one side effect occurred in 81.5% of patients in the terbutaline group and 47.8% in the magnesium group ($p < 0.01$). Finally, the cost for 1 day of magnesium (20 cents) is approximately one third the cost of terbutaline (56 cents). These data suggest that oral magnesium oxide is as effective as terbutaline for the maintenance of tocolysis, with fewer side effects and at a lower cost. (AM J OBSTET GYNECOL 1990;163:879-82.)

Key words: Preterm labor, tocolysis, oral magnesium, oral terbutaline

Patients with successfully arrested preterm labor are generally given oral tocolytic medication until pregnancy is judged to be near term. This oral tocolytic therapy is intended to decrease recurrences of preterm labor and increase the chances of term delivery. β-Sympathomimetic agents are currently the agents of choice for this therapy. However, patients treated with oral β-sympathomimetic agents frequently have unpleasant side effects. Some patients may even discontinue their medication because of the side effects.[1-3] Further, the cost of β-sympathomimetic agents may be prohibitive for some patients.

Recently, oral magnesium has been suggested to be an effective and economical alternative to β-sympathomimetic agents.[3-5] However, there have been no prospective; randomized studies that compare the two drugs. We sought to compare, in a prospective randomized fashion, oral magnesium oxide with oral terbutaline sulfate in the maintenance of tocolysis.

Materials and methods

The study population consisted of 60 preterm labor patients who had labor successfully arrested with parenteral therapy. The study was approved by the Institutional Review Board at The University of Texas Health Science Center at San Antonio. Informed consent was obtained from all patients before entry to the study. The criteria for diagnosis of preterm labor were: (1) gestational age between 25 and 35 weeks as determined by last menstrual period and real-time ultrasonography; (2) three contractions in 20 minutes that persisted despite intravenous hydration with 500 ml of normal saline solution and prolonged sedation with 8 to 20 mg of morphine sulfate; (3) any cervical change.

Table I. Patient characteristics

Days on oral tocolytic agents	28.5 ± 23.1	26.7 ± 18.5	NS
Discontinued therapy (%)	11	9	NS
Cost per day	56 cents	20 cents	—

The choice of parenteral tocolytic agent was at the discretion of the resident physician in charge of the patient's care. After achieving uterine quiescence for 12 to 24 hours, the patients were randomized into one of the two oral tocolytic treatment groups. Group I received magnesium oxide, 200 mg orally every 3 to 4 hours. Patients assigned to Group II received 2.5 to 5 mg of terbutaline sulfate orally every 3 to 4 hours. For the first 24 hours of oral therapy, the patients were maintained on strict bed rest. Light ambulation was begun on the second day. If the patient showed no evidence of recurrent preterm labor, she was discharged at 48 to 72 hours.

Patients were evaluated for recurrent preterm labor during weekly clinic visits. They were questioned concerning side effects and compliance. Patients were specifically asked about experiencing a "fast heart rate," "feeling your heart beating in your chest," nervousness, shaking, nausea, vomiting, diarrhea, or any other symptoms. If a patient failed to attend clinic, she was contacted at home and information concerning side effects was elicited. The patients were maintained on oral tocolytic agents until 36 completed weeks' gestation. Patients who underwent recurrent preterm labor while taking oral tocolytic agents were restarted on parenteral therapy. If treatment was successful they were placed on the oral tocolytic agent to which they were originally randomized.

Statistical analysis was performed with the χ^2 test or the Fisher exact test for categoric variables. For continuous variables, the two-tailed Student t test was used and for interval variables the Wilcoxon rank-sum test was used. An α of <0.05 was considered significant.

Results

Sixty patients were enrolled in the study, with 31 patients in the terbutaline group and 29 in the magnesium group. Ten patients were lost to follow-up or withdrew from the study. Four of these were in the terbutaline group and six were in the magnesium group, resulting in 27 assigned to the terbutaline group and 23 to the magnesium group. As shown in Table I, patient characteristics on entry to the study were comparable between the two study groups. There was one set of twins in each study group.

Fig. 1 displays the difference in side effects between the two groups. Patients in the terbutaline group typically complained of palpitations, fast heart rate, shaking, and nervousness, whereas the magnesium group had diarrhea. Overall, 81.5% of patients in the terbutaline group complained of a least one side effect versus 47.8% in the magnesium group ($p < 0.01$). The number of patients who discontinued therapy because of side effects was not significantly different in the two groups. Pregnancy-outcome parameters were similar

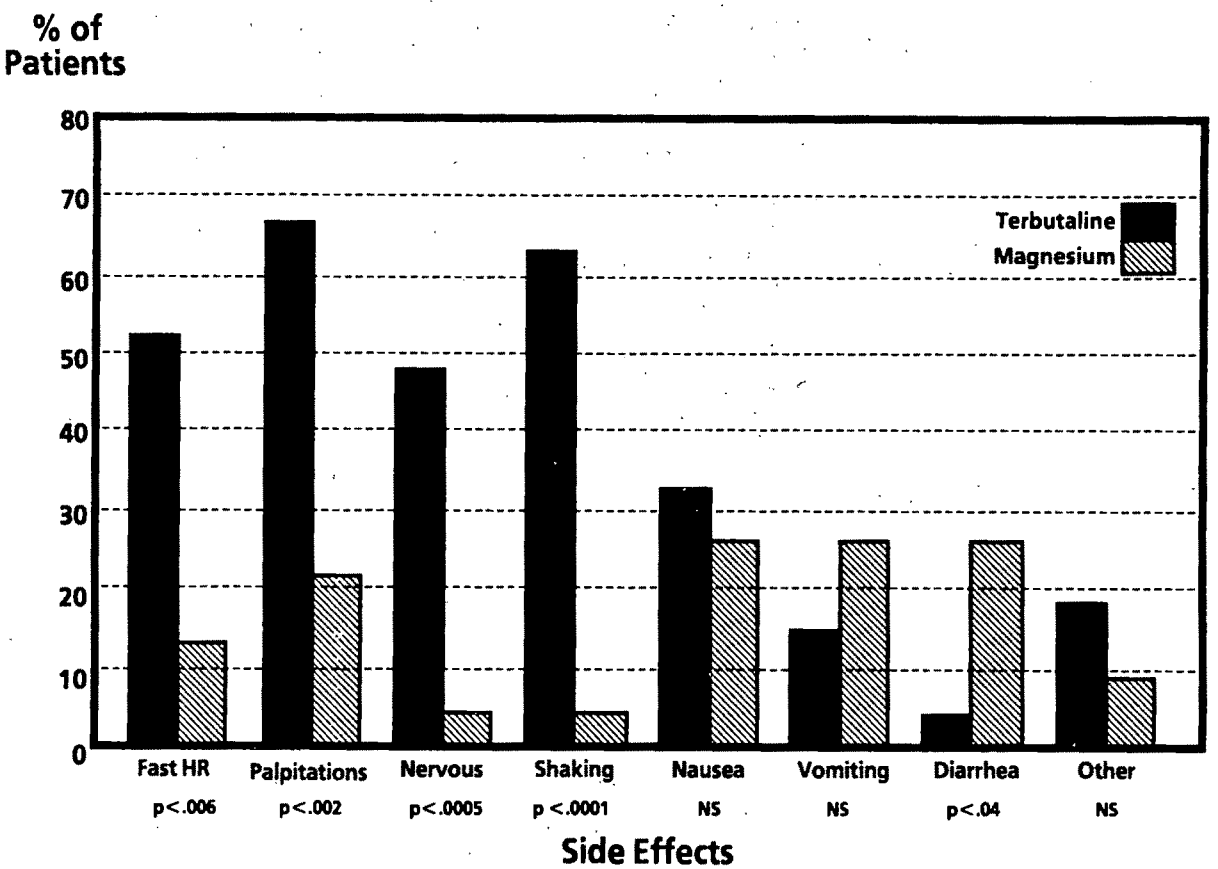

Fig. 1. Percentage of patients reporting side effect with oral terbutaline and oral magnesium oxide.

between groups; however, the daily cost of terbutaline is almost three times that of magnesium (Table II). Likewise, the number of recurrent preterm labor episodes between groups did not differ significantly. There were 11 episodes of recurrent preterm labor in eight patients in the terbutaline group and 13 episodes in eight patients in the magnesium group.

Comment

Our data suggest that oral magnesium oxide is as effective as oral terbutaline for the maintenance of tocolysis. Furthermore, side effects are less common and treatment is less costly when this drug is used.

Oral β-sympathomimetic agents have been shown to be useful in the maintenance of tocolysis. Creasy and associates showed that oral ritodrine significantly lengthened the time between start of oral therapy and first relapse of preterm labor. However, 50% of the patients in the ritodrine group complained of palpitations and flushing, whereas only 33% of the placebo group had similar complaints.[1] Brown and Tejani[2] showed that oral terbutaline, after tocolysis with ethanol, resulted in significantly more time gained in utero than did placebo. No control-group patient complained of palpitations, nervousness, restlessness, or nausea, whereas an average of 10% of the treatment group had at least one of these complaints.[2] Martin and others[3-5] have suggested that oral magnesium salts may be useful for oral maintenance of tocolysis. Martin et al.[3] compared oral ritodrine and magnesium gluconate in a prospective, non randomized manner and found as we did that oral magnesium was as effective as β-sympathomimetics in prolongation of pregnancy. These authors[3] found that 40% of the ritodrine group and 16% of the magnesium group complained of side effects. However, this was not significantly different and patients were not questioned about specific side effects.[3] With regard to efficacy, the power of our study and that of Martin[3] is admittedly low. We had a power of 0.50 to detect a 0.20 difference in the proportion of patients delivered of infants before 36 weeks' gestation.

The diagnosis of preterm labor in our study was made on the basis of the continuation of uterine contractions, despite hydration and sedation, accompanied by any cervical change. This resulted in a high rate (18%) of preterm delivery despite therapy. Our preterm delivery rate is comparable to that in Martin's study[3] (20%). Thus we showed the similar drug effi-

cacies of oral terbutaline and magnesium oxide. In contrast, a higher rate of side effects was found in patients treated with oral terbutaline versus oral magnesium oxide. Indeed, over 80% of the patients in the terbutaline group had at least one side effect. However, both our study and that of Martin[3] were unable to show an increased number of patients who discontinued therapy because of side effects. An additional consideration should be the cost of therapy. Comparison between the drugs reveals that the cost of 1 day of therapy with magnesium oxide (20 cents) is approximately one third the cost of 1 day of therapy with terbutaline (56 cents).

In summary, we believe that oral magnesium oxide is as effective as β-sympathomimetics for the maintenance of tocolysis. Furthermore, maintenance therapy is achieved with a lower incidence of side effects.

We retrospectively studied 209 patients treated with ritodrine hydrochloride to determine whether change in cervical effacement or dilatation during a period of observation before therapy would result in decreased efficacy of ritodrine, as measured by delivery delays of 48 hours, 1 week, or until ≥37 weeks' gestation; neonatal intensive care unit admission; and neonatal respiratory distress syndrome. Patients who were ≥3 cm dilated on admission were at high risk of therapy failure by all outcome measures compared with patients <3 cm dilated. For patients <3 cm dilated on admission, there was no difference in outcome when patients treated for contractions only were compared with those treated after change in effacement or dilatation had been documented. We conclude that awaiting change in cervical effacement or dilatation to be more certain of the diagnosis of preterm labor will not compromise the efficacy of ritodrine tocolysis. (AM J OBSTET GYNECOL 1990;163:882-6.)

Key words: Ritodrine hydrochloride, cervical effacement and dilatation, tocolytic efficacy

The diagnosis of preterm labor is traditionally made by documenting regular uterine contractions accompanied by progressive change in cervical effacement or dilatation during a period of observation.[1] However, when evaluating a patient possibly in preterm labor, clinicians are commonly concerned that awaiting cervical change to be certain of the diagnosis of preterm labor might compromise subsequent tocolytic efficacy.[2] Thus tocolytic medications are frequently administered on recognition of preterm uterine activity, before the documentation of cervical change. This management may result in the exposure of patients who are not in preterm labor to the potential risks of tocolytic medi-

cations. Specifically, clinical experience with ritodrine hydrochloride has resulted in cardiovascular and metabolic toxicities, and maternal deaths have been associated with ridodrine therapy.[3-11]

Ideally, ritodrine would be used only in patients demonstrating "true" preterm labor. Whereas conservatism in administration of ritodrine must be weighed against the concern that awaiting cervical change will reduce tocolytic efficacy, no compelling evidence exists to support either that aggressive tocolysis enhances treatment success or that withholding treatment until cervical change occurs increases treatment failure. This study was undertaken to determine whether tocolysis instituted after documented change in cervical effacement or dilatation is less efficacious than tocolysis instituted only for uterine activity.

Material and methods

Parenteral ritodrine hydrochloride has been the primary pharmacologic treatment of preterm labor at Prentice Women's Hospital and Maternity Center. All patients treated with ritodrine between Jan. 1, 1985, and Dec. 31, 1988, were retrospectively identified. Excluded were patients with ruptured membranes before institution of ritrodrine, treatment before transfer to our institution, treatment with magnesium sulfate before ritodrine, or delivery elsewhere. These exclusions yielded 209 patients who were delivered of 237 infants.

Patients admitted with suspected preterm labor were initially observed for at least 1 hour with bed rest in the left lateral decubitus position, hydration (500 to 1000 ml of isotonic solution over 1 hour), and uterine contraction monitoring. Persistence of regular uterine contractions (all patients had regular uterine contractions at least every 10 minutes; 90% of patients had contractions at least every 5 to 6 minutes) was required for the diagnosis of preterm labor; awaiting change in cervical effacement or dilatation during the period of observation was encouraged but was not required. Whenever possible, serial cervical examinations were performed by a single examiner. Ritodrine was initiated by intravenous pump infusion at 0.10 mg/min and increased by 0.05 mg/min until the minimum dose that maintained uterine quiescence was achieved. After 6 to 12 hours of maintenance intravenous therapy, oral ritodrine hydrochloride was instituted and continued to 36 to 37 weeks' gestation.

Information obtained for each patient included age, race, clinic status (private versus service), prior pregnancy history and complications, medical history, and current pregnancy complications. Gestational age assignment was made on the basis of menstrual dates confirmed by ultrasonography or ultrasonographic age in the absence of a reliable menstrual history. Initial cervical examinations were documented, and any change in cervical effacement or dilatation that occurred before tocolysis was noted.

Table I. Distribution of patients by cervical examination

Admission cervical dilatation (cm)	*No cervical change before tocolysis (No.)*	*Dilatation or effacement before tocolysis (No.)*
0	29	29
>0 to <1	10	16
≥1 to <2	32	22
≥2 to <3	27	8
≥3	32	4

Patients were grouped according to cervical dilatation on admission and by the presence or absence of cervical change before initiation of tocolysis (Table I). Outcome data for the resulting groups were compared including gestational age at delivery; days gained after initial tocolysis; delivery delays of 48 hours, 1 week, or until ≥37 weeks' gestation; necessity of neonatal intensive care unit (NICU) admission; and neonatal respiratory distress syndrome (RDS). Maternal side effects and toxicities deemed significant enough to warrant a change in therapy by the examining physician were noted.

Continuous data were compared with the unmatched Student t test for two samples. Discrete data were investigated with χ^2 and the Fisher exact test where appropriate. Mantel-Haenszel χ^2 was used to detect confounding variables, and therapeutic end points were tested while controlling for confounding variables. A test of trends on the basis of odds ratios determined whether incremental degrees of cervical change after admission increased the risk of tocolytic failure. Trends were tested for significance by corrected χ^2. Stepwise multiple logistic regression tested obstetric, demographic, and historic variables for significant associations with our therapeutic end points. Delivery delays of 48 hours, 1 week, and until term; NICU admission; and RDS were analyzed as dependent variables. In all tests, p values <0.05 were considered statistically significant.

Results

Table II shows that, despite similar risk factors for preterm delivery, patients who were ≥3 cm dilated at admission ($n = 36$) were at significantly increased risk of adverse outcome compared with patients <3 cm dilated ($n = 173$). This occurred despite 89% (32/36) of patients in the ≥3 cm group being treated for contractions only before documented cervical change. Because of the significant risk of therapy failure in the patients ≥3 cm dilated, their inclusion strongly biases

the overall outcome in the group of patients treated before cervical change. To avoid this bias, the 36 patients ≥3 cm dilated on admission were excluded from subsequent analyses.

Of the remaining 173 patients, 98 had no cervical change before tocolysis (group 1), and 75 had documented change in cervical effacement or dilatation before tocolysis (group 2). As depicted in Table III, groups 1 and 2 were similar in gestational age, dilatation, uterine contraction frequency on admission, and risk factors for preterm delivery. Despite cervical change before therapy, group 2 revealed no difference in any outcome parameter compared with group 1. Mantel-Haenszel χ^2 analysis revealed that multiple gestation, clinic status, race, prior preterm delivery, and maternal age <20 years were potential confounding variables. After controlling for these variables there still were no differences in outcomes between group 1 to group 2.

By corrected χ^2 analysis the frequency of each outcome parameter was no different in the patient groups defined by either no change in effacement or dilatation before therapy or by incremental effacement or dilatation (effacement only; >0 but ≤1 or >1 but ≤2 cm dilatation change) before therapy. Likewise, a test of trends detected no increased risk of any adverse outcome with successive increments of cervical effacement or dilatation observed before initiation of tocolysis (Fig. 1).

Stepwise multiple logistic regression indicated that admission cervical dilatation of ≥2 to <3 cm was negatively associated with delivery delays of 48 hours, 1 week, and delivery at term, and positively associated with NICU admission and RDS. Admission dilatation of ≥1 to <2 cm was negatively associated with delivery at term. However, the presence of effacement or dilatation change before therapy, when added stepwise to the model, did not strengthen these associations. No other variables added singly or in combination were significantly associated with the outcomes tested. When evaluated as a single independent variable, cervical change before therapy was not associated with any of the therapeutic end points evaluated.

Because cervical dilatation of ≥2 to <3 cm on admission was associated with adverse outcome on logistic regression, the data were reanalyzed to compare outcome parameters in those with and without cervical change before therapy but <2 cm dilated on admission. The results were unchanged.

A tocolytic side effect or toxicity that prompted a change in therapy was documented in 31 cases (15%). Chest pain, tachycardia, and dyspnea that resolved with reduction or discontinuation of the ritodrine infusion were the most frequent side effects (n = 26), but

pulmonary edema developed in two patients during therapy.

Comment

It is a commonly held opinion that by the time cervical change has been documented it is frequently too late to inhibit preterm labor.[2] This concern motivates physicians to administer ritodrine immediately on documentation of preterm uterine contractions, before documentation of cervical change. However, the effectiveness of ritodrine therapy in the prevention of preterm delivery is controversial. Despite the approval of ritodrine for treatment of preterm labor in 1980, a decrease in the overall prevalence of preterm birth has not been documented.[12] In addition, a meta-analysis of randomized placebo-controlled ritodrine trials by King et al.[13] suggested that ritodrine is somewhat effective in the delay of delivery but not in the prevention of neonatal RDS or death.

The diagnosis of preterm labor is often equivocal. In the 12 trials in King's meta-analysis, a range of 38% to 100% of the controls continued pregnancy for 24 hours; 27% to 89% continued pregnancy for 48 hours; and up to 54% were delivered of infants at term. Uterine activity was necessary for the diagnosis of preterm labor in all studies, and most required some degree of cervical dilatation. Even with cervical dilatation present, either many patients were not in preterm labor, or bed rest alone was an effective treatment for preterm labor. Preterm contractions without documented change in cervical effacement or dilatation would seemingly make the diagnosis of preterm labor even less certain. Despite common concern that cervical change may compromise tocolytic efficacy, to our knowledge this is the first study that objectively addresses this issue.

Our initial analyses revealed that, in contrast to patients with lesser degrees of dilatation, those who presented ≥3 cm dilated were at significant risk of failed tocolysis. Because almost all these patients were treated before documented change in effacement or dilatation, we were unable to evaluate the influence of further cervical change on tocolytic efficacy. However, the high risk of failure after standard tocolytic therapy in this group suggests that patients first seen with preterm labor and advanced dilatation may be ideal candidates for investigation of alternative tocolytic regimens.

A potential for bias exists in any retrospective analysis. The most likely bias in this study would have been toward overtreatment of patients thought to be in preterm labor before documented cervical change (i.e. that some patients in group 1 were not truly in preterm labor). However, this would have tended to show a

much better outcome in group 1 compared with group 2. In fact, this was not the case. Thus our results support equal effectiveness of ritodrine therapy instituted after change in cervical effacement or dilatation compared with therapy instituted without cervical change for those patients first seen <3 cm dilated. Furthermore, our success rate of 89% in the delay of delivery for 48 hours and 50% in the delay of delivery until term in patients who had cervical change before therapy is similar to previously reported success rates.[7] The side effects and toxicities documented in this study and elsewhere underscore the potential risks of ritodrine therapy. These observations suggest that if rationalized only by a presumption of improved efficacy, institution of tocolysis before documented change in effacement or dilatation may not be warranted.

In conclusion, the results of this study show that hydration, rest, and observation is a safe alternative to immediate ritodrine tocolysis for patients who are <3 cm dilated when first seen. If uterine contractions persist and result in cervical change, ritodrine may still be effective.

We gratefully acknowledge Nam Cho, PhD, for his assistance with statistical analyses.

Gram stain results from amniocentesis in patients with preterm premature rupture of membranes—Comparison of maternal and fetal characteristics

Tamerou Asrat, MD, Michael P. Nageotte, MD, Thomas J. Garite, MD, Steven E. Gocke, MD, and Wendy Dorchester, MPH

Orange and Long Beach, California

A total of 108 patients with preterm premature rupture of membranes who had undergone amniocentesis were retrospecively analyzed. Seventy-seven patients had negative amniotic fluid Gram stains and were managed expectantly. Thirty-one patients had positive amniotic fluid Gram stains confirmed by subsequent cultures and were delivered of infants on that basis. A univariate comparison of various parameters revealed significant differences in maternal temperature, pulse, and white blood cell count. Patients with positive Gram stains had lower mean gestational age, higher baseline fetal heart rate, and nonreactive fetal heart rate tracings. On the basis of a multivariate stepwise discriminate analysis, fetal heart rate >150 beats/min or nonreactive nonstress test were the best predictors of the Gram stain findings, with a sensitivity of 71%, specificity of 76%, and negative predictive value of 87%. These data suggest that in patients with preterm premature rupture of membranes and fetal tachycardia or nonreactive nonstress test, amniocentesis should be performed in the initial evaluation. (Am J Obstet Gynecol 1990;163:887-9.)

Key words: Premature rupture of membranes, Gram stain, fetal tachycardia, nonreactive nonstress test, infection

Rupture of membranes in preterm gestation remains a major contributor to perinatal morbidity and mortality as a result of complications of prematurity and sepsis.[1] The management of these patients has focused on identification of potentially infected fetuses and adjustment of management decisions on the basis of the results of diagnostic amniocentesis and ultrasonography.[2-9] This retrospective study compares maternal and fetal characteristics in patients with preterm premature rupture of membranes (PROM) and negative amniotic fluid Gram stains with patients with preterm PROM and positive amniotic fluid Gram stains to identify those characteristics that could be incorporated in a statistical model that would be predictive of Gram stain findings.

Material and methods

Charts of patients admitted to Long Beach Memorial Women's Hospital between 1984 and 1988 for preterm PROM and who had amniocentesis were reviewed. Only singleton pregnancies from 24 to 36 weeks' gestation not in labor on admission were included in the study. Patients with chorioamnionitis, bleeding, fetal distress, and those who had received antibiotics, glucocorticoids, or β-sympathomimetic agents were excluded.

Rupture of membranes was documented by sterile speculum examination with pooled fluid, ferning, and nitrazine paper determination. Electronic fetal monitoring was used to establish the presence of fetal distress and document uterine activity. Ultrasonographic evaluation was used in the assessment of gestational age and performance of amniocentesis. Amniotic fluid was sent for fetal lung maturity studies, Gram stain, and aerobic and anaerobic cultures. Patients with mature lung profiles were delivered of infants by oxytocin induction or by cesarean section if obstetrically indicated. Patients with positive Gram stains were begun on parenteral antibiotics and delivered of infants. Patients with negative amniotic fluid Gram stains and immature lung profiles were managed expectantly with daily nonstress test (NST) surveillance as described previously.[10]

Statistical analyses were made with the pooled Student *t* test and the Fisher exact test where applicable. A multivariate stepwise discriminate analysis was done with BMDP-7 statistical software (Regents University of California, Berkley, Calif., 1988). And α level of 0.05 was considered significant. All tests were made against a two alternative sided hypothesis.

Results

A total of 108 patients met with the study criteria and were included in the analysis. Seventy-seven patients

Nonreactive	—	$n = 0$	—	$n = 9$	0.000005

*Taken within 1 hour of the amniocentesis.
†Degrees Centigrade.
‡Latency period from time of PROM to amniocentesis.
§Acceleration of ≥15 beats/min for ≥15 seconds.

Table II. Predictive value of FHR > 150 and nonreactive NST

	Sensitivity (%)	*Specificity (%)*	*Predictive value*	
			Positive (%)	*Negative (%)*
FHR > 150	68	77	54	86
Nonreactive NST	29	100	100	78
FHR > 150 or nonreactive NST	71	76	55	87

had negative amniotic fluid Gram stains and were managed as outlined above. Thirty-one patients had positive amniotic fluid Gram stains and cultures and were delivered of infants on the basis of the Gram stain results.

Univariate comparisons of certain maternal and fetal characteristics were made as shown in Table I. All parameters were obtained within 1 hour of the amniocentesis. There were significant differences in maternal temperature, pulse, and white blood cell count ($p < 0.0005$, $p < 0.044$, and $p < 0.011$, respectively) between patients with negative and positive Gram stains. Patients with positive Gram stains had a lower mean gestational age, higher baseline fetal heart rate (FHR), and higher incidence of nonreactive FHR tracings ($p < 0.001$, $p < 0.0005$, and $p < 0.000005$, respectively). A multivariate stepwise discriminate analysis was performed. The two variables with the best predictive value of Gram stain results were FHR >150 beats and nonreactive NST (Table II) (F statistical value $2102 = 25.3$, $p < 0.0005$). On the basis of the results of the discriminate analysis, the sensitivity, specificity, and positive and negative predictive values of elevated baseline FHR or nonreactive NST were calculated (Table II).

Comment

A tremendous divergence of opinion exists concerning the proper management of rupture of membranes remote from term. Several authors have advocated the use of amniocentesis in patients with preterm PROM to assess both pulmonary maturity and the microbiologic status of amniotic fluid.[2,3,8,9] This approach identifies and allows for expectant management of the noninfected patient. More recently Vintzileos et al.[4,6,7] and Goldstein et al.,[5] proposed the use of the biophysical profile in the management of these patients, predicated on the assumption that fetuses within a noninfected amniotic cavity behave differently from fetuses exposed to intraamniotic infections. These studies showed that fetuses in an infected environment have lower overall biophysical profiles, with decreased fetal breathing and movements. The present analysis supports these reports in that fetuses that reside in a colonized milieu will often manifest characteristics that are different from fetuses in an uninfected amnioitic cavity. In the present study the patients with positive Gram stains and culture had a significantly lower gestational age than that of those with negative Gram stains (30.5 weeks versus 32.4 weeks). Whereas it is true that there is a

maturational process that occurs in the baseline FHR and FHR acceleration with advancing gestational age, the difference in mean gestational age of 1.9 weeks seen between the gram-positive and gram-negative groups is not great enough to account for the statistically significant difference in FHR reactivity and baseline heart rate observed between the two groups.[11]

Because amniocentesis is invasive and difficult to perform in patients with PROM (especially those with very low fluid volume), many clinicians do not include amniotic fluid Gram stain and culture in the routine assessment of patients with preterm PROM. The diagnosis of early or subclinical chorioamnionitis, although desirable, is difficult in the absence of fever. Symptoms such as leukocytosis are quite nonspecific. The data presented here would support that the presence of fetal tachycardia (FHR > 150 beats/min) and nonreactive FHR tracing is highly suggestive of occult intraamniotic infection, and that amniocentesis to verify this suspicion is warranted.

We thank Lanie M. Adamson, MS, Linda Salyer, and Elaine Baker for their assistance.

Adjusting the loading dose of magnesium sulfate for tocolysis

Jeffrey W. Wright, MD, Louis E. Ridgway III, MD, and Robert M. Patterson, MD
San Antonio, Texas

The purpose of this prospective study was to establish a method to calculate a loading dose of magnesium sulfate so as to achieve therapeutic levels of tocolysis more quickly. Fifty patients in preterm labor were enrolled. In the first phase 25 patients were studied so that the apparent volume of distribution for the loading dose of magnesium sulfate could be estimated and an adjusted loading dose could be calculated. The efficacy of this adjusted loading dose was then tested on a further 25 patients in the second phase. We found that the apparent volume of distribution could be accurately estimated and an adjusted loading dose calculated, with the use of ideal body weight, degree of underweight, and current use of β-sympathomimetics. In the adjusted loading dose group therapeutic levels were achieved more often, with higher postloading magnesium levels and a greater decrease in contraction index immediately after the loading dose. We conclude that an adjusted loading dose can be calculated for magnesium sulfate to optimize tocolytic therapy. (AM J OBSTET GYNECOL 1990;163:889-92.)

Magnesium sulfate is a commonly used parenteral tocolytic. It has been shown to be as effective as β-sympathomimetics with a lower incidence of serious side effects.[1-3] However, a longer period of time is required to achieve uterine quiescence with magnesium than with β-sympathomimetics.[1]

Several studies have demonstrated a need to achieve

a minimum therapeutic concentration of magnesium ions to suppress uterine activity.[1, 4-6] However, these levels are rarely achieved with the typical 4 gm loading dose of magnesium sulfate.[5] To achieve a therapeutic level of magnesium while avoiding potential toxicity, knowledge of the volume of distribution of magnesium is needed. However, no previous studies address the issue of the volume of distribution for the loading dose of magnesium sulfate in patients in preterm labor.

The goal of this study was to establish the apparent volume of distribution of the loading dose of magnesium sulfate so that an adjusted loading dose could be calculated and to investigate the efficacy of this adjusted loading dose.

Material and methods

In this prospective study, 50 patients admitted to the labor and delivery unit with preterm labor were enrolled. Preterm labor was defined as a gestational age of 24 to 35 weeks and regular uterine contractions accompanied by documented cervical change. Choice of tocolytic agent was by individual physician preference. In general, magnesium is used in our institution as the first-line drug for tocolysis. Patients with preexistent renal disease, suspected dehydration, or a contraindication to tocolysis were excluded.

The study was done in two phases with 25 patients in each phase. In phase I patients were given a 4 gm loading dose of magnesium sulfate ($MgSO_4 \cdot 7H_2O$ United States Pharmacopeia) infused intravenously over 15 minutes with an infusion pump. Blood samples for serum magnesium determination were drawn immediately before and 1 minute after the loading dose was given. Magnesium levels were determined by means of the calmagite reaction and a Paramax System (Baxter Scientific, Irvine, Calif.). Apparent volume of distribution (AVOD) was calculated by the equation: AVOD = $MgSO_4$ loading dose [grams] $\times 98$ [milligrams Mg++ per gram $MgSO_4$ / (Postloading level − preloading level [milligrams per deciliter]) $\times 100$ ml/dl. This formula reduced to: AVOD = 39,200/(Postloading level-Preloading level). Because patients in preterm labor often receive significant volumes of intravenous fluids before tocolysis AVOD was corrected by the following equation: True AVOD = Measured AVOD − (Intravenous fluids − Urine output).

For each patient, height, weight, ideal body weight, degree of weight over or under the ideal, gestational age, body surface area, presence of multiple gestation, previous exposure to magnesium, and current therapy with β-sympathomimetic tocolytics were recorded. Ideal body weight was estimated by a modified 1983 Metropolitan life table. This table was generated by taking the midpoint of the range of ideal weight for a given height and frame size, converting it to kilograms, and correcting for lack of shoes and clothing (Table I). For overweight patients, overweight was calculated by: Overweight = Actual weight − Ideal weight. For underweight patients underweight was calculated by: Underweight = Ideal weight − Actual weight.

Contraction monitor strips for 30 minutes before the loading dose began and 30 minutes after completion were photocopied for future analysis. After completion of the study, two blinded examiners scored the monitor strips for contraction index and number of contractions in 30 minutes. The contraction index was calculated as the total duration of contractions during 30 minutes of monitoring.

Stepwise linear regression was used to establish the relationship between apparent volume of distribution and the independent variables weight, ideal weight, underweight, overweight, body surface area, multiple gestation, previous exposure to magnesium, and current therapy with β-sympathomimetics.

In phase 2, apparent volume of distribution was estimated by the equation established in phase 1: AVOD = 613.1 + 215.7 (Ideal weight in kilograms) + 408.3 (Underweight in kilograms) − 2182.7 (if receiving β-sympathomimetic). The adjusted loading dose was calculated by this equation: Loading dose = AVOD [milliliters] × 5.2 [Expected change in serum Mg++] / (98 [milligrams Mg++ per gram $MgSO_4$] × 100 [milligrams per deciliter]). The simplified equations are shown in Table II. We assumed an approximate baseline level of 1.8 mg/dl and target level of 7 mg/dl. The minimum therapeutic level was defined as 6 mg/dl. Magnesium infusion technique, as well as other treatment and data collection, was identical to that of phase 1.

After phase 2 was completed, stepwise linear regression was again performed with study phase added as

Table II. Calculation of the adjusted loading dose

Apparent volume of distribution = 613.1 + 215.7 (Ideal weight, kilograms) + 408.3 (Underweight, kilograms) − 2182.7 [If receiving β-sympathomimetic]
Adjusted loading dose [grams] = 0.00053 × Apparent volume of distribution

*Appropriate safety precautions should be observed during magnesium infusion.

an independent variable. This was done to control for possible effects of higher loading doses on apparent volume of distribution.

Comparison of the groups was done by Student's t test for continuous variables and χ^2 or Fisher's exact test for categorical variables. Stepwise linear regression was performed with the use of the variables as described above. Both forward and backward stepping procedures were used and generated identical methods. A BMDP statistical package was used for all statistical analysis with α of <0.05 considered significant.

Results

Patient characteristics were similar between the two groups with two exceptions (Table III). There were more underweight patients in phase 1 and a tendency toward use of magnesium as a first-line tocolytic in phase 2.

Stepwise linear regression of phase 1 data revealed that previous magnesium exposure, multiple gestation, actual weight, body surface area, or overweight had no effect on AVOD. The significant predictive variables were ideal weight (kilograms), underweight (kilograms), and current therapy with β-sympathomimetics related by the equation: AVOD = 613.1 + 215.7 (Ideal weight) + 408.3 (Underweight) − 2182.7 (if receiving β-sympathomimetic), $r = 0.61$, $p = 0.04$. Ideal weight from the modified 1983 Metropolitan life table was the best predictive factor. Furthermore, the negative regression coefficient for current therapy with β-sympathomimetics indicates that patients being treated with β-sympathomimetics had lower apparent volumes of distribution ($p = 0.045$).

Baseline magnesium levels and apparent volume of distribution were similar between phases. Postloading magnesium levels were significantly higher in phase 2 ($p < 0.001$) (Table IV).

As shown in Table V, the ability of the regression equation to choose an adjusted loading dose was demonstrated by a greater number of phase 2 patients who were above the therapeutic minimum level ($p = < 0.001$). Further, there was a greater decrease in contraction index ($p = 0.01$), suggesting improved

Table III. Patient characteristics

tocolytic effects with the adjusted loading dose. The correlation between observers was 0.78 for contraction index and 0.88 for contractions per 30 minutes. Although more patients in phase 2 had successful delay of delivery for 48 hours, this did not reach significance.

Most patients in both phases experienced cutaneous flushing during infusion of the loading dose. Two patients in each group had severe nausea and vomited. No signs of magnesium toxicity, including loss of patellar reflexes, were seen. In addition, no serious side effects, such as pulmonary edema, were encountered in either phase.

Comment

We found that the apparent volume of distribution for magnesium can be estimated with clinical parameters. With this information we were able to calculate an adjusted loading dose of magnesium sulfate to achieve therapeutic levels quickly in most patients. Furthermore, this adjusted loading dose had a greater effect on contraction index in the immediate postloading period.

As expected, ideal body weight was the most powerful predictor of apparent volume of distribution. After establishing the regression equation to predict apparent volume of distribution, we attempted to use alternative

Table V. Effects of loading dose

methods to estimate ideal body weight. These included the equation Ideal weight = 100 lb + 5 lb per inch of height greater than 5 feet, as well as corrections for pregnancy weight gain. None of these was as effective as the modified 1983 Metropolitan life table.

Interestingly, our regression model of apparent volume of distribution indicates that patients being treated with β-sympathomimetic tocolytics have a lower apparent volume of distribution for magnesium. Eleven of the patients in our study were being treated with β-sympathomimetics. Medication was changed to magnesium sulfate when the β-sympathomimetic agent failed to achieve tocolysis. β-Sympathomimetic tocolytics are usually associated with increased intravascular volumes.[7] However, magnesium is distributed far beyond the intravascular space, as indicated by an average apparent volume of distribution of 12.6 L. It is possible that β-sympathomimetics interfere with the entry of magnesium into cells and thus reduce total apparent volume of distribution.

A tendency toward use of magnesium sulfate as the initial tocolytic was seen in phase 2. Although that may bias the results concerning effects on contractions, apparent volume of distribution should not be affected, as current β-sympathomimetic therapy and phase of study were both used as independent variables during regression modeling. The slight tendency toward underweight patients in phase 1 seems to be a chance occurrence.

We excluded patients with renal disease or suspected dehydration because such patients may have lower apparent volumes of distribution resulting in excessively high postloading magnesium levels. None of the study patients experienced loss of patellar reflexes or other signs of magnesium toxicity. However, the potential for toxicity exists with any infusion of magnesium. Thus we recommend appropriate safety precautions be taken when an adjusted loading dose is used.

Several investigators have suggested the need to achieve a minimum serum level of magnesium to produce tocolysis. Harbert el at.[4] have shown that magnesium, at levels of 6 to 8 mEq/L (7.2 to 9.4 mg/dl), reduced uterine activity in monkeys, patients with preeclampsia and isloated myometrial strips. In a clinical study of preterm labor Elliott[5] found that levels of 5 to 7 mg/dl were effective for tocolysis. Hollander et al.[1] found the mean serum level to achieve tocolysis was 6.6 mg/dl. This group was a target serum magnesium concentration of 6 to 8 mg/dl. In a review of tocolytic agents, Caritis et al.[6] state that the labor-inhibiting level is 5.5 to 7.5 mg/dl. Our data demonstrate a greater reduction in contraction index with higher postloading magnesium levels. This suggests that quickly achieving a therapeutic magnesium level is desirable.

Some authors[6] have suggested using a 6 gm magnesium sulfate loading dose. Twenty-four of 25 patients in phase 2 received an adjusted loading dose of > 6 gm. Using apparent volumes of distribution obtained in phase 2, we estimate that only 19 of 25 patients would have achieved a level above 6 mg/dl after a 6 gm loading dose. Thus it seems that a loading dose of 6 gm would be better than 4 gm in most patients. However, using a 6 gm dose in a small patient who is receiving β-sympathomimetics may place that patient at high risk for toxicity. Therefore an adjusted loading dose technique may offer a balance of safety and efficacy.

Magnesium has been demonstrated to be equally as efficacious and to have fewer side effects than do β-sympathomimetics.[1-3] However, there is difficulty in achieving tocolysis quickly. This delay in tocolysis may be related to a delay in achieving therapeutic levels. Our data suggest that loading doses can be calculated for each patient in preterm labor to achieve therapeutic serum levels almost immediately. Further study is needed to determine the safety of this adjusted loading dose and whether it will improve the success of tocolytic therapy.

Infants of diabetic mothers with accelerated fetal growth by ultrasonography: Are they all alike?

James D. Keller, MD,[a] Boyd E. Metzger, MD,[b] Sharon L. Dooley, MD,[a] Ralph K. Tamura, MD,[a] Rudy E. Sabbagha, MD,[a] and Norbert Freinkel, MD,[b]†

Chicago, Illinois

We studied longitudinal ultrasonographic growth patterns (abdominal circumference, biparietal diameter) initiated early in gestation in 52 pregnancies complicated by pregestational diabetes mellitus and 19 controls. Three predominant patterns of growth were ascertained including a heretofore unrecognized pattern characterized by accelerated abdominal circumference growth (>90th percentile) before 24 weeks' gestational age. Maternal and neonatal anthropometric and metabolic parameters were contrasted for the three patterns. The findings suggest that in some cases of diabetic macrosomia that can be recognized before 24 weeks' gestation, augmented growth may be influenced by factors other than fetal hyperinsulinism. (AM J OBSTET GYNECOL 1990;163:893-7.)

Key words: Evolving macrosomia, diabetes mellitus, amniotic fluid insulin

Macrosomia has long been considered the hallmark of diabetic fetopathy. The Pedersen hypothesis[1] proposed nearly four decades ago links fetal hyperinsulinism induced by altered maternal metabolism to accelerated fetal growth and resultant macrosomia. Although macrosomia has traditionally been defined on the basis of birth weight, it has long been recognized that the infant of a diabetic mother typically has a disproportionate increase in such insulin-sensitive tissue as adipose, liver, and muscle but not in tissue such as bone, skull, and brain in which growth is relatively insulin insensitive.[2, 3] Accordingly, evolving macrosomia in utero has been detected by accelerated fetal abdominal circumference growth, a measurement that reflects insulin-sensitive tissue.[4-6]

Whereas there is experimental evidence in support of this pathophysiologic sequence, there has been limited reported success in the prediction of macrosomic fetal growth on an individual basis from conventional measure of maternal metabolic control. Whether this is a result of variability in the response of an individual fetus to its maternal metabolic milieu, limitations in the conventional tools used to assess metabolic effects on the fetus, or other reasons is not clear. Our objective was to examine whether all macrosomic infants of diabetic mothers conform to the same pattern of accelerated fetal growth and whether this pattern reflected measures of maternal metabolic control and fetal hyperinsulinism.

Material and methods

A group of 52 pregestational insulin-dependent patients enrolled in the Diabetes in Pregnancy Center of Northwestern University between September 1977 to April 1983 met the following criteria: (1) two or more ultrasonographic examinations including both abdominal circumference (AC) and biparietal diameter (BPD) measurements, one ≤24 weeks' gestation (AC_1, BPD_1) and one ≥32 weeks' gestation (AC_2, BPD_2) gestation; (2) gestational age at delivery of ≥36 weeks' gestation. Nineteen women with normal carbohydrate metabolism as documented by the 3-hour oral glucose tolerance test according to the criteria of O'Sullivan and Mahan[7] and who exhibited normal ultrasonographic growth throughout pregnancy were included as controls. Each BPD measurement was made at the level of the thalami and the AC measurement was made at the level of the umbilical vein in the fetal liver. Growth percentiles were determined by plotting the individual measurements on growth charts derived from pregnancies at the same institution.[8]

Fasting plasma glucose values were drawn at each outpatient visit and at least twice weekly during hospitalization, and analyzed by the glucose oxidase method. With one exception all diabetic patients were hospitalized at least twice during pregnancy, once at enrollment and a terminal admission before delivery. Hemoglobin A_{1c} was measured monthly with column

*Designated study group growth patterns: normal growth (I), late accelerated growth (II), and early accelerated growth (III).

chromatography.[9] Mean values for hemoglobin A_{1c} were derived for individual subjects by averaging all measurements obtained during each trimester. Mean values for fasting plasma glucose were calculated for each trimester from all outpatient values and from two values each week drawn on predetermined days during hospitalization. An overall pregnancy mean (mean of trimester means) was also derived for each patient. Patients underwent amniocentesis to evaluate fetal lung maturity at 34 to 38 weeks' gestation. Amniotic fluid insulin was measured by double antibody immunoassay and amniotic fluid glucose was measured by a glucose oxidase method.[10-12] If a patient had more than one amniocentesis, the maximum amniotic fluid insulin and amniotic fluid insulin/glucose ratio was used. Control patients underwent similar metabolic evaluation excluding amniocentesis and first-trimester fasting plasma glucose and hemoglobin A_{1c} measurements. All protocols were approved by the Institutional Review Board, and appropriate patient consents were obtained.

The following anthropometric variables were examined: maternal height and prepregnancy percent ideal body weight, neonatal birth length, birth weight, and birth symmetry index (weight ÷ weight at 50th percentile/length ÷ length at 50th percentile).[13] A symmetry index >1.2 was used to define macrosomia in this study. Gestational age was assigned on the basis of menstrual dates confirmed by ultrasonography, or by ultrasonography in the absence of reliable menstrual dates. Birth weight and birth length percentile ranks were derived from Lubchenco.[14]

As can be seen in Table I, nine theoretic patterns of fetal growth were considered on the basis of AC percentile at the time of AC_1 (<24 weeks) and AC_2 (>32 weeks). Each of the 52 infants of diabetic mothers was assigned to an ultrasonographic growth pattern without knowledge of metabolic and anthropometric data. Three predominant patterns of growth were ascertained: group I (AC_1 ≤90th, AC_2 ≤90th), denoted normal growth; group II (AC_1 ≤90th, AC_2 >90th), denoted late accelerated growth; group III (AC_1 >90th, AC_2 >90th), denoted early accelerated growth. These three growth patterns included 47 of 52 infants of diabetic mothers. Analyses were on the basis of these 47 infants of diabetic mothers and the 19 control patients. Data were analyzed with the two-tailed Student t test, χ^2 or analysis of variance with posthoc Duncan comparison where appropriate.

Results

The maternal and neonatal anthropometric data for the three study groups and controls are presented in Table II. Those infants with normal abdominal circumference growth (group I, $n = 17$) were similar in weight and length to control infants. In contrast the infants of diabetic mothers in those groups with early (group III, $n = 13$) and late (group II, $n = 17$) accelerated AC growth had neonatal anthropometrics suggestive of diabetic macrosomia on the basis of birth weight and symmetry index of >1.2.

Examination of metabolic parameters (Table III) showed that all conventional measures of maternal metabolic control (i.e., fasting plasma glucose and hemoglobin A_{1c} levels) were significantly different in infants of diabetic mothers than in controls. However, infants of diabetic mothers from all groups had similar fasting plasma glucose and hemoglobin A_{1c} levels despite the described differences in neonatal anthropometrics. The mean number (± 1 SD) of fasting plasma glucose values in each patient used to generate average fasting plasma glucose were 23 ± 6.3 and 13.6 ± 2.5 in diabetic patients and controls, respectively. As expected, group II with late accelerated AC growth had measures of amniotic fluid insulin that tended to be higher than those in group I (normal growth).

Group III (early accelerated growth) was different in several respects. Amniotic fluid insulin and amniotic fluid insulin/glucose ratio was more similar to group I (normal growth) despite neonatal anthropometrics consistent with macrosomia. In addition, 6 of 13 infants in this group III had a biparietal diameter that exceeded the 90th percentile after 32 weeks' gestation (BPD_2 >90th). This finding occurred in only 1 of 34 infants of diabetic mothers in groups I and II ($p < 0.05$) and prompted stratification of group III on the basis of normal BPD growth (BPD_2 <90th, III-A) or accelerated BPD growth (BPD >90th III-B). Infants in group III with normal BPD growth (III-A) exhibited high hemoglobin A_{1c} levels in the first trimester and tended to have elevated amniotic fluid insulin and amniotic fluid insulin/glucose ratio in the third trimester (Table IV). By contrast, those with accelerated BPD growth (III-B) had significantly lower maximal and first-trimester hemoglobin A_{1c} and did not exhibit elevated amni-

otic fluid insulin and amniotic fluid insulin/glucose ratio. Furthermore those infants with accelerated BPD growth were born to mothers who tended to be tall and lean.

Comment

Previous studies have shown that ultrasonography can detect evolving macrosomia in the fetus of a diabetic mother. In an earlier report from this center, Ogata et al.[4] described two patterns of fetal growth in pregnancy complicated by diabetes. One pattern was indistinguishable from that seen in nondiabetic pregnancies. The other pattern, designated as having accelerated growth on the basis of a disproportionate increase in abdominal circumference, resulted in heavier and fatter infants with evidence of augmented fetal islet function. Landon et al.[5] confirmed Ogata's findings, but neither study related growth to detailed measures of maternal metabolic control. We have now correlated fetal growth patterns to maternal metabolism. Our measures of maternal metabolic control were limited to fasting plasma glucose levels and hemoglobin A_{1c} because at the time this study was undertaken postprandial glucose measurements were not routinely performed. Fasting plasma glucose values obtained at predetermined regular intervals throughout gestation were used to generate average fasting plasma glucose values to characterize the maternal metabolic milieu. All values from weekly or biweekly outpatient visits were included. However, only two per week from inpatients were used so as not to bias the data with values obtained during relatively short periods of intense monitoring.

Our group has reported elevated levels of cord

plasma C-peptide and amniotic fluid insulin in association with higher birth weight in pregnancies complicated by mild gestational diabetes mellitus (GDM with fasting plasma glucose values <105 mg/dl) as well as in those with more severe GDM or pregestational insulin-dependent diabetes mellitus. This promoted the suggestion that fetal islet function may be exquisitely sensitive to alterations in maternal metabolism that are not appreciated by present methods of assessing metabolic control that focus exclusively on glucoregulation. The findings in the present report are consistent with that premise. The infants of diabetic mothers of group II (typical diabetic fetopathy) had the highest amniotic fluid insulin and insulin/glucose concentration, indicating fetal hyperinsulinism. However, their third-trimester glycemic control was good as evidenced by fasting plasma glucose values and hemoglobin A_{1c} not distinguishable from those of group I whose growth pattern was normal and amniotic fluid insulin level only mildly elevated.

The infants in our study who showed normal fetal AC growth (group I) and late accelerated AC growth (group II) conformed to those patterns first described by Ogata. Group I had birth anthropometrics indistinguishable from controls. Group II were heavier and fatter (symmetry index, 1.29) and showed evidence of fetal hyperinsulinism. The opportunity to analyze serial measurements starting earlier in pregnancy than in previous studies in a group restricted to pregestational diabetic patients provided an opportunity to identify a third pattern of growth not recognized heretofore. These fetuses showed acceleration of AC growth before 24 weeks' gestation, which was sustained at >90th percentile (Group III). The birth weight and symmetry index of these infants of diabetic mothers were similar to those of infants in whom accelerated AC growth was not detected until later in gestation. However, group III was also heterogeneous with respect to BPD growth. Those with normal BPD growth tended to have evidence of fetal hyperinsulinism and neonatal anthropometrics typical of diabetic fetopathy. Furthermore, the hemoglobin A_{1c} values suggest that these women may have been in poorer control early in pregnancy. It should be noted that this was the only subset in which conventional measurements of maternal metabolic control may have indicated that the group was at risk of macrosomia.

Six of 13 group III patients with early accelerated AC growth (group III-B) also had accelerated growth of the biparietal diameter. These infants of diabetic mothers were also disproportionately heavy (symmetry index, 1.4). Whether this truly represents adiposity typical of diabetic fetopathy cannot be determined. There was no evidence of poor metabolic control in the first trimester as in group III-A and amniotic fluid insulin measurements were similar to concentrations we have found in normal nondiabetic pregnancies.[11] Furthermore, the mothers of these infants tended to be the tallest and leanest of any subset, an indication that these infants may have been destined to be large on the basis of genetic or other factors.

In summary, most of our infants of diabetic mothers

experienced longitudinal growth patterns consistent with those previously described. However, we also identified a group of infants of diabetic mothers that exhibited excessive abdominal circumference growth earlier than predicted (i.e., before 24 weeks' gestation). Within this group, those with normal biparietal diameter growth showed heightened islet cell function similar to that previously described in diabetic fetopathy and found in our group II with classic diabetic macrosomia. Those with accelerated biparietal diameter growth had increased birth weight and high symmetry index as expected but without evidence of fetal hyperinsulinism. Whether this pattern represents a previously unrecognized or variable response to early derangements in maternal metabolism or an expression of genetically determined accelerated growth potential remains to be established.

We gratefully acknowledge our many colleagues at the Northwestern University Diabetes in Pregnancy Center who participated in the clinical management of these patients, especially Dr. R. Phelps in Medicine, Drs. R. Depp and M. Socol in Obstetrics, and Drs. E. Ogata and J. Boehm in Neonatology. We are also indebted to the nursing staff of the Clinical Research Unit at Northwestern Memorial Hospital and to Mr. Goeff Page and others members of the biometry core of the Diabetes in Pregnancy Center for statistical analysis of the data.

Prevalence and etiology of respiratory distress in infants of diabetic mothers: Predictive value of fetal lung maturation tests

Siri L. Kjos, MD, Frans J. Walther, MD, PhD, Martin Montoro, MD, Richard H. Paul, MD, Fidelia Diaz, MA, and Mary Stabler, BS

Los Angeles, California

The purpose of this study was to investigate the prevalence of respiratory distress syndrome attributable to surfactant deficiency in infants of diabetic mothers tested for fetal lung maturation. Three tests were assessed: (1) lecithin/sphingomyelin ratio, (2) phosphatidylglycerol concentration, and (3) optical density at 650 nm. From January 1987 through June 1989, 526 diabetic gestations were delivered within 5 days of fetal lung maturation testing. Surfactant-deficient respiratory distress syndrome was present in five infants (0.95%); all were <34 weeks' gestational age. Other causes of respiratory distress were transient tachypnea of the newborn (n = 5), hypertrophic cardiomyopathy (n = 4), pneumonia (n = 2), polycythemia (n = 1), and meconium aspiration syndrome (n = 1). The use of standard maturity values of lecithin/sphingomyelin ratio ≥ 2.0, phosphatidylglycerol > 2% to 5%, and optical density at 650 nm ≥ 0.150 were evaluated. Each test had a 100% sensitivity in identifying surfactant-deficient respiratory distress syndrome and a 100% negative predictive value in identifying the absence of disease. All three tests had a low positive predictive value: 15% for lecithin/sphingomyelin ratio, 9% for phosphatidylglycerol, and 3% for optical density at 650 nm. We concluded that most cases of respiratory distress in the infants of diabetic mothers were unrelated to surfactant deficiency. The standard maturity values used in fetal lung maturation tests were valid in the diabetic gestation. The optical density at 650 nm was useful as a first-line test to predict the absence of surfactant-deficient respiratory distress syndrome. (Am J Obstet Gynecol 1990;163:898-903.)

Key words: Respiratory distress syndrome, diabetes in pregnancy, fetal lung maturation, surfactant deficiency

Respiratory distress syndrome (RDS) describes a constellation of clinical findings in which the cardinal signs are tachypnea, expiratory grunting, nasal flaring, and costal retractions. Its cause is deficient surfactant production (as established by amniotic fluid analysis) producing decreased lung compliance with resultant hypoxia.[1] Surfactant-deficient RDS has been reported to occur more frequently in infants of diabetic mothers. The ability to determine the lecithin/sphingomyelin (L/S) ratio has offered the clinician a means to prevent iatrogenic prematurity while avoiding intrauterine death in diabetic pregnancies. Several earlier studies have supported a delayed biochemical maturation of the fetal lung in the "uncomplicated" diabetic gestation.[2-6] Phosphatidylglycerol heralds the final step in fetal lung maturation.[7] It has been suggested that the presence of phosphatidylglycerol assures the absence of surfactant-deficient RDS in infants of diabetic mothers.[3-7] More recently, however, the evidence of delayed fetal lung maturation in diabetic gestations has not been substantiated.[8-11] Two reports failed to demonstrate differences in fetal lung maturation among diabetic gestations relative to classification.[8,9] In addition, delays in maturation of the L/S ratio or in the appearance of phosphatidylglycerol could not be demonstrated in diabetic gestations when compared with normal gestations.[9-11]

Other obstetric advances have facilitated safer expectant management and thus have contributed to a reduced prevalence of RDS in infants of diabetic mothers. These include improved methods of glycemic control, more accurate dating of gestational age by ultrasonography, antepartum fetal surveillance, and improved neonatal care. These factors were examined by Mimouni et al.,[12] who concluded that diabetes, as currently managed, did not increase the risk for development of surfactant-deficient RDS.

The purpose of this study was to investigate the oc-

currence of respiratory distress attributable to surfactant deficiency in infants of diabetic mothers relative to three methods of fetal lung maturation testing.

Material and methods

Study population. During the study period (January 1987 through June 1989), 1830 women whose pregnancies were complicated by diabetes were delivered at Women's Hospital, 584 of whom (32%) underwent amniotic fluid evaluation of fetal lung maturation. Of these, 526 were delivered of their infants within 5 days and were included in final analysis. Ninety-five percent of the study patients had a Spanish surname. Fetal lung maturation testing was undertaken more frequently in women with insulin-requiring diabetes: 17% of those with class A_1 were tested, compared with 47% of those with class A_2, 51% of those with class B, and 53% of those with class C through R during this period. The composition of the study population consisted of 22% class A_1 ($n = 114$), 68% class A_2 ($n = 358$), 6% class B ($n = 31$), and 4% class C through R ($n = 23$). Premature delivery before 37 completed weeks occurred in 82 patients (16%), 12 (2%) of whom were delivered before 34 completed weeks.

Pregnancy management. Patients with class A_1 gestational diabetes mellitus were managed with measurement of weekly fasting serum glucose levels, with values maintained at <105 mg/dl by diabetic diet therapy. Patients with class A_2 gestational diabetes mellitus (fasting serum glucose level ≥ 105 mg/dl) were evaluated by home capillary blood glucose monitoring four to six times a day; they maintained euglycemic blood glucose control by a combination of diet and insulin therapy. Patients with class B through R were followed up similarly to class A_2 patients but insulin regimens and monitoring of vascular complications were individualized as needed.

Indications for delivery and fetal lung maturation evaluation in term gestations (after 37 completed weeks, $n = 444$) were elective delivery (96%) and poor maternal glycemic control (4%). Indications in preterm gestations ($n = 82$) were labor (53%), rupture of membranes (23%), pregnancy-induced hypertension (8%), abnormal antepartum testing results (6%), and poor maternal glycemic control (4%). Amniotic fluid specimens from six patients with premature rupture of membranes were obtained from perineal pad extraction, as described by Golde.[13] The determination of optical density at 650 nm (OD_{650}) was not performed on these perineal pad specimens or on those contaminated by blood ($n = 8$) or meconium ($n = 26$). Clinically the value of OD_{650} was used as a rapid screening test when test results were necessary for immediate obstetric management. An OD_{650} value ≥0.150 was considered mature.[14] This was performed first by the house staff in 28 patients on the labor floor and later confirmed by the laboratory. No cases of false mature tests occurred, nor was there a significant difference between house staff and laboratory results. The laboratory value was used for analysis in this study. In nonemergent cases, the results of the L/S ratio and phosphatidylglycerol were used. Mature values were considered to be L/S ratio ≥ 2.0 and phosphatidylglycerol ≥ 2% to 5%.[7]

Outcome of neonates. The hospital courses of all infants were reviewed for confirmation of diagnosis with a staff neonatologist (F. J. W.) who was blinded to the fetal lung maturation test results. Those infants exhibiting signs of respiratory distress (tachypnea, expiratory grunting, nasal flaring, costal retractions, or cyanosis) are described in this study. Surfactant-deficient RDS was diagnosed with these criteria: (1) onset of clinical symptoms within 6 hours of life, with supplemental oxygenation required at >24 hours of life and peak severity at 2 to 3 days of life, and (2) chest x-ray film with diffuse reticulogranular pattern in both lung fields with superimposed air bronchograms.[1] Other causes of respiratory distress distinguished from surfactant-deficient RDS were transient tachypnea of the newborn, hypertrophic cardiomyopathy, pneumonia, meconium aspiration, and polycythemia (venous hematocrit ≥ 65%). Gestational age at delivery was determined by the clinical parameters of menstrual age, clinical age at first visit, and first ultrasonographic examination and subsequent growth pattern. In all cases there was correlation with neonatal estimation by Dubowitz score of gestational age within 2 weeks.

Performance of fetal lung maturation tests. All tests were performed in a certified pathology laboratory by a medical technologist. The lung profile was obtained with the two-dimensional thin-layer chromatography technique with acetone precipitation of disaturated lecithin (dipalmitoyl phosphatidylcholine) as described by Kulovich et al.[7] The OD_{650} was measured on uncontaminated, centrifuged (2000 *g* for 10 minutes) amniotic fluid with a Bausch-Lomb spectrophotometer (No. 20, at 340 to 800 nm) as described by Sbarra et al.[14]

Statistical analysis. Comparisons between mean values of continuous variables (e.g., OD_{650}, percent phosphatidylglycerol, L/S ratio, gestional age at delivery) and diabetic class were analyzed by analysis of variance. The correlation of immature test values and the presence or absence of surfactant-deficient RDS was assessed by Fisher's exact test. Sensitivity (percent of immature tests in infants with surfactant-deficient RDS), specificity (percent of mature tests in infants without surfactant-deficient RDS), positive predictive value (percent of surfactant-deficient RDS in infants with immature tests), and negative predictive values (percent without surfactant-deficient RDS in infants with mature

tests) were determined.[15] The test efficiency (True positive plus True negative/Total) also was calculated.

Results

One complication (1/526) from amniocentesis, a transplacental "bloody tap," occurred. Persistent fetal bradycardia and bleeding from the placental site was visualized on ultrasonography, necessitating emergency cesarean section. This neonate had a hematocrit of 29% and exhibited hypovolemic shock with metabolic acidosis, necessitating dopamine administration and blood transfusion. The infant responded well and was discharged home on the third day of life.

Eighteen neonates had signs of respiratory distress consisting of tachypnea, grunting, costal retractions, or cyanosis, occurring within the first 6 hours of life and requiring further workup. Causes of these symptoms are presented in Table I and discussed below.

Surfactant-deficiency RDS (cases 1 to 5). Surfactant-deficient RDS was present in five (0.95%) infants. Three of them had severe surfactant-deficient RDS with one dying on the first day of life and the other two requiring oxygen therapy for 26 and 31 days. The remaining two had mild surfactant-deficient RDS, both requiring oxygen for the first 48 hours. One of these infants also had apnea-bradycardia spells that necessitated aminophylline therapy during the first month of life.

Transient tachypnea of the newborn (cases 6 to 10). Five infants were diagnosed with transient tachypnea of the newborn. All were born via cesarean section, four before labor and the fifth during early labor with intervention for fetal distress. They were rapidly weaned off supplemental hood oxygen within the first 6 hours of life. Chest x-ray films showed areas of atelectasis in four of the five cases.

Hypertrophic cardiomyopathy (cases 11 to 14). Four of the infants with respiratory distress were diagnosed by echocardiogram to have hypertrophic cardiomyopathy (with intraventricular septal hypertrophy). Chest x-ray films showed pulmonary edema in two cases and cardiac enlargement in the third. No infant had signs of sepsis, shock, or asphyxia. Two of these infants required oxygen therapy after the first day of life. One infant (case 14) had respiratory distress and a diffuse granular pattern on chest x-ray film. The clinical course, coupled with an echocardiographic persistence of hypertrophic cardiomyopathy at 16 days of life and the failure of an increase in positive inspiratory pressure to improve oxygenation, implicated a cardiogenic origin of the respiratory distress. All of the four mothers of these infants initially were seen for prenatal care with overt fasting hyperglycemia (137 to 228 mg/dl). Two of these mothers (cases 11 and 12) had late entry into prenatal care and late diagnosis of diabetes; they were begun on insulin at 30 and 25 weeks, respectively. Patients 13 and 14 both presented for care and had the diagnosis made in the first trimester. However, both were extremely noncompliant with prenatal care, diet, and insulin therapy.

Pneumonia (cases 15 and 16). Two infants were diagnosed with pneumonia. One had β-hemolytic streptococcal bacteremia and required oxygen therapy by hood for 2 days. The second was born to a mother admitted with premature rupture of the membranes and amnionitis. She received intrapartum antibiotic therapy. The infant's chest x-ray film showed a bilateral diffuse granular pattern with a right upper lobe infiltrate. The infant's clinical course was consistent with pneumonia necessitating oxygen therapy by hood for 7 days.

Of the remaining two symptomatic infants (cases 17 and 18), one was first seen with tachypnea requiring oxygen by hood for the first 6 hours of life. This infant had polycythemia (hematocrit 66%) and required a partial exchange transfusion. The other had severe meconium aspiration syndrome with acidosis, shock, and persistent fetal circulation.

Correlation of tests with surfactant-deficient RDS. All 526 specimens had an L/S ratio and phosphatidylglycerol determined. Forty-four (8.3%) of the samples, including three of the five infants with surfactant-deficient RDS, were contaminated. None of these infants with contaminated specimens who had an L/S ratio ≥2.0 or phosphatidylglycerol ≥5% exhibited surfactant-deficient RDS ($p < 0.01$). There was a significant correlation between all three tests and the development of surfactant-deficient RDS (Fisher's exact test, $p < 0.02$, Table II). All three tests had a 100% sensitivity (all infants with surfactant-deficient RDS were identified by immature test values) and had 100% negative predictive values (no infants with mature test values had surfactant-deficient RDS). The specificity of all tests was relatively high, probably reflecting the fact that 85% of the infants were born at term (i.e., after 37 completed weeks). Surfactant-deficient RDS was not present in any term infants. In the limited number of infants with fetal lung maturation evaluations who were delivered before 34 weeks' gestation, 42% (5/12) exhibited surfactant-deficient RDS.

The L/S ratio had the best positive predictive value, but it was still very poor (15%). The lowest positive predictive value (3.2%) was seen with the OD_{650}. With a mature OD_{650} value ≥ 0.150, only 5 of 419 (1.2%) had an L/S ratio < 2.0 ($p < 0.001$). The presence of phosphatidylglycerol did not improve the predictive ability of the L/S ratio. In all cases where phosphatidylglycerol was present, the L/S ratio was >2.0. Overall, the L/S ratio had the greatest test efficiency of 94.7%, compared with phosphatidylglycerol (90.5%) and OD_{650} (86.9%).

†American College of Obstetricians and Gynecologists modification of White diabetic classification (A_1, A_2, B, or C) is listed.

RDS did not develop in any of the 58 infants not delivered within 5 days of fetal lung maturation. Sixty-four percent had a mature L/S ratio, with 85% delivered within 14 days of amniocentesis. The mean number of days to delivery was 12 and the mean gestational age at amniocentesis was 37 weeks. The delay in delivery was primarily due to lack of labor room space for elective induction. Of the 36% with an immature L/S ratio, 51% were delivered within 14 days of amniocentesis with the mean number of days to delivery being 18 and the mean gestational age at amniocentesis being 36 weeks.

Table II. Comparison of predictive ability of three tests for fetal lung maturation. Actual numbers of patients are presented as ratios in parentheses below calculated value of predictive test

Test	*Sens.*	*Spec.*	*PPV*	*NPV*	*Efficiency*	*p**
L/S ratio < 2.0	100%	94.6%	15.0%	100%	94.7%	<0.001

	2/2	419/480	2/61	419/419	421/482	

Sens., Sensitivity; *Spec.*, specificity; *PPV*, positive predictive value; *NPV*, negative predictive value.
*Fisher's exact p value for the association of each test with the development of surfacant deficient RDS.

There was no significant difference in mean gestational age (±SEM) at time of delivery between the various diabetic classes: class A_1, 38.0 ± 0.2 weeks; class A_2, 38.0 ± 0.1 weeks; class B, 37.0 ± 0.5 weeks; classes C through R, 37 ± 0.3 weeks. Likewise, the mean value for all three tests (L/S ratio, percent phosphatidylglycerol, and OD_{650}) did not differ significantly among the diabetic classes ($p > 0.10$).

Comment

Of the 18 infants evaluated for signs of respiratory distress, only five were found to have surfactant-deficient RDS (<1%); all five were delivered before 34 weeks' gestational age. Other causes were responsible for respiratory distress in the remaining 13 infants. The five infants with transient tachypnea of the newborn were delivered via cesarean section. A complicating finding was that four of the infants with symptoms were found to have hypertrophic cardiomyopathy with intraventricular septal hypertrophy. Without a high degree of suspicion by the clinican and echocardiography, this complication of diabetes could easily be attributed to surfactant-deficient RDS. All four were subject to poor maternal glycemic control, either from late diagnosis with marked fasting hyperglycemia or from poor therapeutic compliance. This association between septal hypertrophy is well correlated with poor maternal diabetic control and fetal hyperinsulinemia.[16-20] Last, pneumonia was also found to be a cause of significant respiratory distress in two of the infants, both of whom required oxygen.

This study confirms the use of standard maturity values of L/S ratio ≥ 2.0, phosphatidylglycerol > 2% to 5%, and OD_{650} ≥ 0.150 as valid in the diabetic pregnancy. All infants with surfactant-deficient RDS were identified by immature values with each of the three tests (sensitivity = 100%), while surfactant-deficient RDS was not seen in any infants with mature tests. This study extends the application of the OD_{650} to the diabetic pregnancy as an ideal primary test.[21-25] It is rapid, and inexpensive, and it maintains a high negative predictive value.

In summary, in this large clinical series managed by current obstetric standards, surfactant-deficient RDS was rare in the infants of diabetic mothers. The majority of infants exhibiting signs of respiratory distress did not have immature lung development with insufficient surfactant production. Furthermore, surfactant-deficient RDS was not present in any term infants. We suggest it is time to reevaluate the need for fetal lung maturation testing in term, currently managed diabetic pregnancies.

The relationship between maternal serum and amniotic fluid α-fetoprotein in women undergoing early amniocentesis

Cynthia G. Brumfield, MD, Gretchen A. Cloud, MS, Richard O. Davis, MD, Sara C. Finley, MD, John C. Hauth, MD, and Larry Boots, PhD
Birmingham, Alabama

α-Fetoprotein levels were measured on 148 paired samples from the maternal serum and amniotic fluid in women ≥age 35, who were undergoing early amniocentesis (12 to 14 weeks) for chromosomal analysis. These 148 women were white, weighed <200 pounds, had no serious medical problems, and did not have a fetal abnormality detected by ultrasonography or karyotype analysis. There was a significant rise in the maternal serum α-fetoprotein concentration from 12 to 14 weeks' gestation. Amniotic fluid α-fetoprotein peaked at 13 weeks and then significantly declined by 14 weeks' gestation. Similar to reports from normal pregnancies at 16 and 17 weeks, we found no correlation between the maternal serum and amniotic fluid α-fetoprotein levels between 12 and 14 weeks. Amniotic fluid α-fetoprotein levels cannot be predicted by levels in the maternal serum in pregnancies between 12 and 14 weeks' gestation. (AM J OBSTET GYNECOL 1990;163:903-6.)

Key words: Maternal serum, amniotic fluid, α-fetoprotein

Recently new techniques such as chorionic villus sampling[1] and early amniocentesis[2] have been developed that allow genetic disorders to be diagnosed in the first trimester. It has been predicted that the use of these procedures will make first-trimester prenatal diagnosis the norm for the 1990s.[3] A possible advantage of early amniocentesis over that of chorionic villus sampling is the use of amniotic fluid α-fetoprotein (AFP) analysis to detect a fetal neural tube defect. Amniotic fluid AFP medians have been reported in gestations from 11 to 15 weeks in over 1000 pregnancies.[4] However, the reliability of maternal serum or amniotic fluid AFP to accurately diagnose open spine disorders in these early pregnancies is still under investigation.[5, 6] Whereas Barford et al.[7] found no correlation between maternal serum and amniotic fluid AFP at 16 and 17 weeks' gestation, this relationship has not been ascertained in earlier gestations of 11 to 14 weeks.

To assess the correlation between AFP levels in the

Table I. Mean AFP levels in maternal serum and amniotic fluid with standard errors

Gestation (wk)	n	Maternal serum AFP (ng/ml)		Amniotic fluid AFP (μg/ml)	
		Mean	SEM	Mean	SEM
12	25	15.96	1.25	18.20	0.94
13	38	20.96	1.13	21.58	0.72
14	85	28.63	1.62	18.14	0.58

maternal serum and amniotic fluid compartments, we reviewed the records of women who underwent an early amniocentesis (11 to 14 weeks) at our institution during a 1-year period. The relationship between AFP in the maternal serum and amniotic fluid in these pregnancies form the basis of our report.

Material and methods

An early amniocentesis, in our study population, was defined to be from 11 through 14 completed weeks of gestation when the amniocentesis was performed. Before each amniocentesis a maternal serum sample was obtained for an α-fetoprotein assay. An ultrasonographic examination was then performed to document fetal viability and to confirm gestational age. If the best estimate of gestational age by ultrasonography agreed within 7 days of a reliable last menstrual period, then the menstrual dates were used to date the pregnancy. If the menstrual dates were uncertain or if the best estimate of gestational age by ultrasonography varied by more than 7 days from the last menstrual period, then the ultrasonographic best estimate of gestational age was used to date the pregnancy.

Amniocentesis was performed by standard technique with a 22-gauge needle and ultrasonographic guidance. A total of 15 ml of amniotic fluid was withdrawn for a fetal karyotype analysis and an amniotic fluid AFP assay. The AFP samples from the maternal serum and amniotic fluid on each patient were measured in the same reference laboratory with an enzyme immunoassay technique (Abbott polyclonal). The intraassay and interassay coefficients of variation on the AFP samples reported in our study were 6.4% and 7.1%, respectively.

From Aug. 1, 1988, through July 31, 1989, after Institutional Review Board approval, women were prospectively identified and informed consent was obtained for an early genetic amniocentesis. Patients were included if they were white, weighed <200 pounds, had no serious medical problems, and had a singleton gestation between 11 and 14⅞ weeks' gestation. Patients were excluded from analysis if a fetal ultrasonogram or chromosomal abnormality was identifed or if they were at increased risk of having an infant with a neural tube defect.

Analysis of variance with Duncan's multiple range test was used to compare serum and amniotic fluid AFP levels at each week of gestation. Pearson's correlation coefficient was used to define the relationship beween maternal serum and amniotic fluid AFP levels.

Results

One hundred forty-eight paired maternal serum and amniotic fluid AFP samples were obtained at 12, 13, and 14 weeks' gestation. Patients seen at 11 weeks' gestation were excluded because of insufficient numbers. These 148 women all had an early amniocentesis for advanced maternal age. The mean maternal age was 37 years. All infants born to these women were normal at birth with no evidence of a neural tube defect.

Mean AFP levels in the serum and amniotic fluid with standard errors at each week of gestation are listed in Table I. Maternal serum AFP values were significantly higher at week 14 than at weeks 12 and 13 ($p = 0.0001$; by analysis of variance). Amniotic AFP values were significantly higher at week 13 than at weeks 12 and 14 ($p = 0.002$; by analysis of variance). Fig. 1 depicts the relationship between maternal serum AFP and amniotic fluid AFP in gestations from 12 to 14 weeks. No correlation between AFP levels in the serum and amniotic fluid compartment was noted ($r = -0.071$).

Comment

It has been shown by the study of human fetuses[8] that serum levels of AFP rapidly increase each week of gestation beginning at 6 weeks and reaching a maximal concentration at 13 weeks. The rapid increase in AFP concentration during this time in gestation is thought to correlate with the rapid growth of the fetal liver, the primary source of AFP production.[9]

Crandall et al.[4] reported that the amniotic fluid AFP levels parallel the levels in fetal serum from 11 to 15 weeks' gestation, although at approximately 120 times lower in concentration. These levels peak at 13 weeks and then decline by 10% each week thereafter. AFP levels in our 148 amniotic fluid samples from 12 to 14 weeks' gestation confirmed this relationship.

Hay et al.[10] reported that maternal serum AFP in normal human pregnancies could be detected by radioimmunoassay as early as 10 weeks' gestation and gradually rose each week in gestation until a peak level was obtained at 32 weeks. Our data and those of others[11, 12] confirm that maternal serum AFP levels rise each week of gestation beginning in the first trimester.

Barford et al.[7] found no relationship between maternal serum and amniotic fluid AFP in 297 paired serum and amniotic fluid samples from normal pregnancies at 16 to 17 completed weeks of gestation. To date, this relationship between the serum and amniotic fluid AFP compartments has not been assessed in ear-

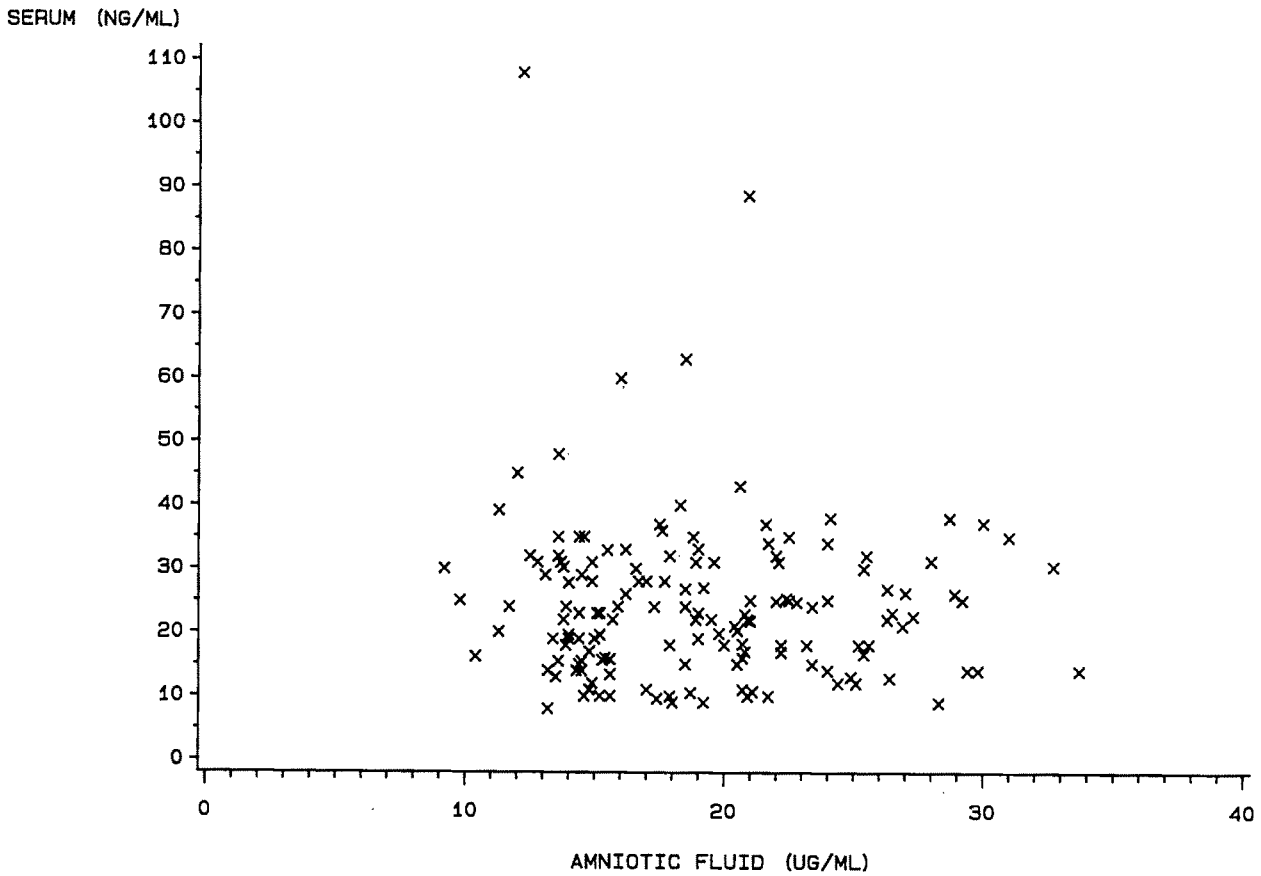

Fig. 1. Relationship between maternal serum AFP and amniotic fluid AFP in gestations between 12 and 14 weeks.

lier gestations. In this study we could not find a statistical relationship between maternal serum and amniotic fluid AFP levels in 148 paired samples obtained from 12- to 14-week gestations.

Mears et al.[13] used iodine 125–labeled AFP during the last trimester of pregnancy in the pregnant ewe to demonstrate rapid transplacental transfer of AFP between the fetal and maternal serum. However, there was much slower transfer between the amniotic fluid and fetal and maternal serum. It was therefore concluded that the transfer of AFP between the fetus and mother is transplacental rather than transamniotic during the last third of pregnancy and that amniotic fluid AFP is a static pool when compared with AFP in fetal and maternal blood. In humans it has not been clearly defined how α-fetoprotein passes from the fetal compartment into the maternal serum. The absence of a relationship between AFP levels in the maternal serum and amniotic fluid compartments, as described by Barford et al.[17] at 16 and 17 weeks and by our study at 12 to 14 weeks' gestation, suggests, even as early as 12 weeks' gestation, that the placenta, the amnion, or both regulate this protein interchange.

The lack of a correlation between maternal serum and amniotic fluid in gestations from 12 to 14 weeks precludes the use of maternal serum AFP levels to predict amniotic AFP levels in women undergoing an early amniocentesis or perhaps a chorionic villus sampling. Although the predictive value for a fetus with a neural tube defect of either maternal serum or amniotic fluid AFP is not known for gestations before 14 weeks, fetal chromosomal aneuploidies have been found in association with low maternal serum AFP levels in pregnancies from 8 to 11 weeks' gestation.[12, 14] Sufficient studies relating elevated levels of maternal serum AFP with neural tube defects in the first trimester are not available, and large population studies will be required to determine the sensitivity and specificity of maternal serum AFP testing to detect open spine defects or other fetal anomalies in these early gestations. The reliability of amniotic fluid AFP determinations in early pregnancies to diagnose neural tube defects will be determined in part by the accuracy of acetylcholinesterase analysis to aid in the diagnosis of these disorders.[5, 6]

In summary, we could not find a correlation between AFP levels in the maternal serum and amniotic fluid in women undergoing genetic amniocentesis at 12 to 14 weeks' gestation. AFP levels in the maternal serum in

these early gestations cannot be used to predict AFP levels in the amniotic fluid.

Perinatal outcome of forty-nine pregnancies complicated by acardiac twinning

Thomas R. Moore, MD, Scott Gale, MD, and Kurt Benirschke, MD
San Diego, California

Acardiac twinning affects 1 in 100 monozygotic twin pregnancies and 1 in 35,000 pregnancies overall. The presence of an acadiac twin requires the normal (or "pump") twin to provide circulation for itself, as well as the acardiac sibling. In many cases the acardiac twin is almost equal in size to the normal twin. The principal perinatal problems associated with acardiac twinning are pump-twin congestive heart failure, maternal hydramnios, and preterm delivery. We reviewed the perinatal courses of 49 acardiac twin pregnancies to identify factors prognostic of favorable outcome. The overall perinatal mortality was 55%, primarily associated with prematurity. Mean (±SD) gestational age at delivery was 29 ± 7.3 weeks, with a mean (±SD) normal twin weight of 1378 ± 1047 gm. The acardiac weight averaged 651 ± 571 gm. However, the occurrence of hydramnios, the occurrence of preterm labor, and perinatal outcome were strongly related to the ratio of the acardiac and pump-twin's weight. The mean overall ratio of the twin weights was 52% ± 42%. However, the mean weight ratio for patients delivered before 34 weeks was 60% versus 29% ($p < 0.04$). Preterm delivery was strongly associated with the development of hydramnios and congestive heart failure in the pump twin ($p < 0.01$). If the twin-weight ratio was above 70% (25% of cases), the incidence of preterm delivery was 90%; hydramnios, 40%; and pump-twin congestive heart failure, 30% compared with 75%, 30%, and 10%, respectively, when the ratio was less ($p < 0.05$). Regression of the weight of the acardiac twin against its longest dimension (L) resulted in this equation for prediction of acardiac weight: Weight (grams) = $1.2\ L^2 - 1.7L$; $r = 0.79$, $p < 0.01$. These data suggest that estimation of the relative weights in acardiac twins provides prognostic information regarding outcome. Poor outcome occurs with congestive heart failure and hydramnios in the normal twin. Use of the above data may assist in counseling patients and determining optimal management. (Am J Obstet Gynecol 1990;163:907-12.)

Key words: Acardiac, twins, hydramnios

Acardiac twinning is a rare complication of multifetal gestation occurring in 1% of monozygotic twin pregnancies and 1 of 35,000 pregnancies overall.[1, 2] The presence of an acardiac twin requires the normal (or "pump") twin to provide circulation for itself as well as the acardiac sibling. In many cases the acardiac twin is equal in size to or larger than the normal co-twin. The principal perinatal problems associated with acardiac twinning are pump-twin congestive heart failure, maternal hydramnios, and preterm delivery.[3] Frequently these events occur in the periviable period (22 to 26 weeks). We therefore reviewed the obstetric histories and neonatal courses of 49 cases of acardiac twinning to identify factors prognostic of favorable outcome.

Methods

Cases were collected from records of in-born pregnancies at the University of California San Diego and from the case files of one of the authors (K. B.). For each case the maternal delivery record, pump-twin neonatal record and pertinent autopsy and pathologic reports were obtained.

Gestational age at delivery was determined by best obstetric dates supplemented with the Dubowitz score. The diagnosis of hydramnios was based on the clinical impression of the attending obstetrician together with sonographic reports. The diagnosis of pump-twin congestive heart failure was based on clinical observations by the attending neonatologist, and/or radiographic-sonographic evidence of cardiomegaly with coexisting ascites or edema and/or autopsy findings.

Twin-weight ratio was computed as the weight of the acardiac twin expressed as a percentage of the pump-twin weight. A total of 33/49 (66%) pregnancies contained adequate data for this analysis.

The data were collected in a microcomputer database

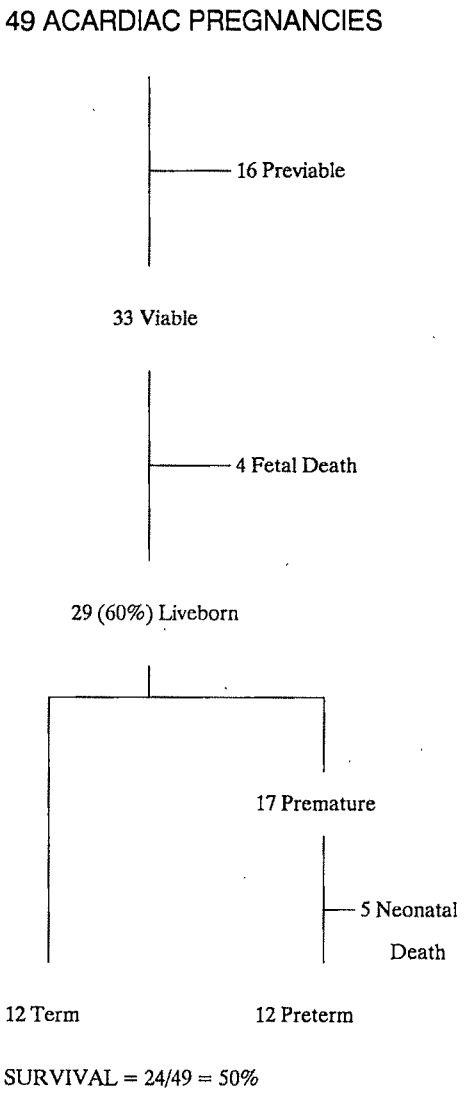

Fig. 1. Schematic of pregnancy outcome for 49 cases of acardia. Viability is defined as delivery at or beyond 25 weeks.

Table I. Perinatal complications of 49 pregnancies with acardiac twinning

Delivery mode	
Spontaneous abortion	18%
Elective termination	14%
Cesarean section, all cases	38%
Cesarean section, potentially viable cases	58%
Pump twin	
Male/female	57%/43%
Malpresentation	29%
Major structural anomaly	9%
Hydramnios	46%
Congestive heart failure	53%
Previable	32%
Live-born	59%
Premature (<37 wk)	35%
Gestational age at delivery (wk)	29 ± 7
Birth weight (gm)	
Acardiac	651 ± 571
Pump-twin	1378 ± 1047

*Mean ± SD.

and analyzed with χ^2 with Yates' correction and the Student t test where appropriate. A p value of <0.05 was considered significant.

Results

Considering the entire data set, the mean maternal age was 26 ± 5.7 years (±SD). A total of 49% of the gravid women were primiparous; 46 of 49 cases (94%) involved twin gestation with two cases occurring in triplets and one in quadruplets.

The obstetric and neonatal course of 49 pregnancies with acardiac twinning is schematized in Fig. 1. One third of infants were delivered before viability was reached (25 weeks). Of the potentially viable pregnancies, 12% ended in pump-twin death in utero. In all, 12 of 49 (24%) were delivered live and mature, but they accounted for only 36% of the potentially viable pregnancies. Newborn intensive care unit admission was required in 41% of the pregnancies and 59% of those reaching viability. Five pump twins died in the neonatal period (10% overall; 17% of potentially salvageable infants), resulting in survival of only 24 pregnancies (50%).

Complications during pregnancy and the newborn period are summarized in Table I. One third of pregnancies resulted in spontaneous or voluntary abortion. Vaginal delivery was achieved in one third of the total, but more than half of potentially viable pregnancies required cesarean section. Transverse or breech positioning (33%) and fetal distress (30%) were major contributors to the high rate of operative delivery.

Hydramnios was a major maternal complication, occurring in 40% of all acardiac pregnancies. Hydramnios was associated strongly with preterm labor and pump-twin congestive heart failure. Eighty-two percent of patients with hydramnios experienced preterm labor requiring hospital admission and treatment, compared with a rate of 22% in pregnancies with normal amniotic fluid ($p < 0.01$). Similarly, excessive amniotic fluid was observed in 78% of pump twins with congestive heart failure, compared with 13% of those in whom congestive heart failure was not confirmed ($p < 0.001$).

Since hydramnios and pump-twin congestive heart failure were strongly associated with prematurity, the predictive ability of the twin weight ratio was compared to outcome. For all cases the twin weight ratio was 52% ± 8% (mean ± SEM). Fig. 2 illustrates the distribution of cases with and without pump-twin congestive heart failure with various values of the twin weight ratio. The mean twin weight ratio in cases of congestive heart failure was 88% ± 8.2% while the ratio in cases without congestive heart failure was only 21% ± 5% ($p < 0.0001$). Cases without pump-twin heart failure are clustered below twin weight ratio values of 80%.

The frequency of hydramnios with various twin weight ratios is tabulated in Fig. 3. The mean twin

Fig. 2. Acardiac/pump-twin weight ratio and occurrence of congestive heart failure in pump twin. *Open bars* are cases with pump-twin congestive heart failure. Weight ratio is acardiac weight expressed as percentage of pump-twin weight.

weight ratio for cases of hydramnios was 81% ± 8% versus 44% ± 9% in those without ($p < 0.005$). When the twin weight ratio was computed for pregnancies with and without preterm delivery (60% ± 2% vs 25% ± 2%) and neonatal intensive care unit admission (71% ± 3% vs 40% ± 2%), the relative size of the acardiac twins was highly predictive ($p < 0.001$).

Considering cases with twin weight ratios >50% (70% of cases), the frequency of hydramnios, pump-twin congestive heart failure, and prematurity was 44%, 25%, and 94% compared with 18%, 0%, and 35% when the ratio was less. The sensitivity, specificity, and predictive value of twin weight ratio >50% for selected outcome variables is presented in Table II. The sensitivity for detection of hydramnios and preterm delivery is above 80%. While the specificity and positive predictive power are statistically significant ($p < 0.05$), the values are modest (56% to 70%). With regard to twin weight ratio prediction of a live outcome, the sensitivity, specificity, and predictive power are all poor and not statistically significant.

Nevertheless, the risk of prematurity was linearly related to twin weight ratio. The week of delivery for each case is plotted against twin weight ratio in Fig. 4. The mean (±SD) gestational age at delivery was 29 ± 7.3 weeks, but premature deliveries tended to occur most frequently when the twin weight ratio was >60%. The negative slope of the regression line (Weeks at delivery = 37-6.9 × twin weight ratio) is statistically significant ($r = 0.57$; $p < 0.05$).

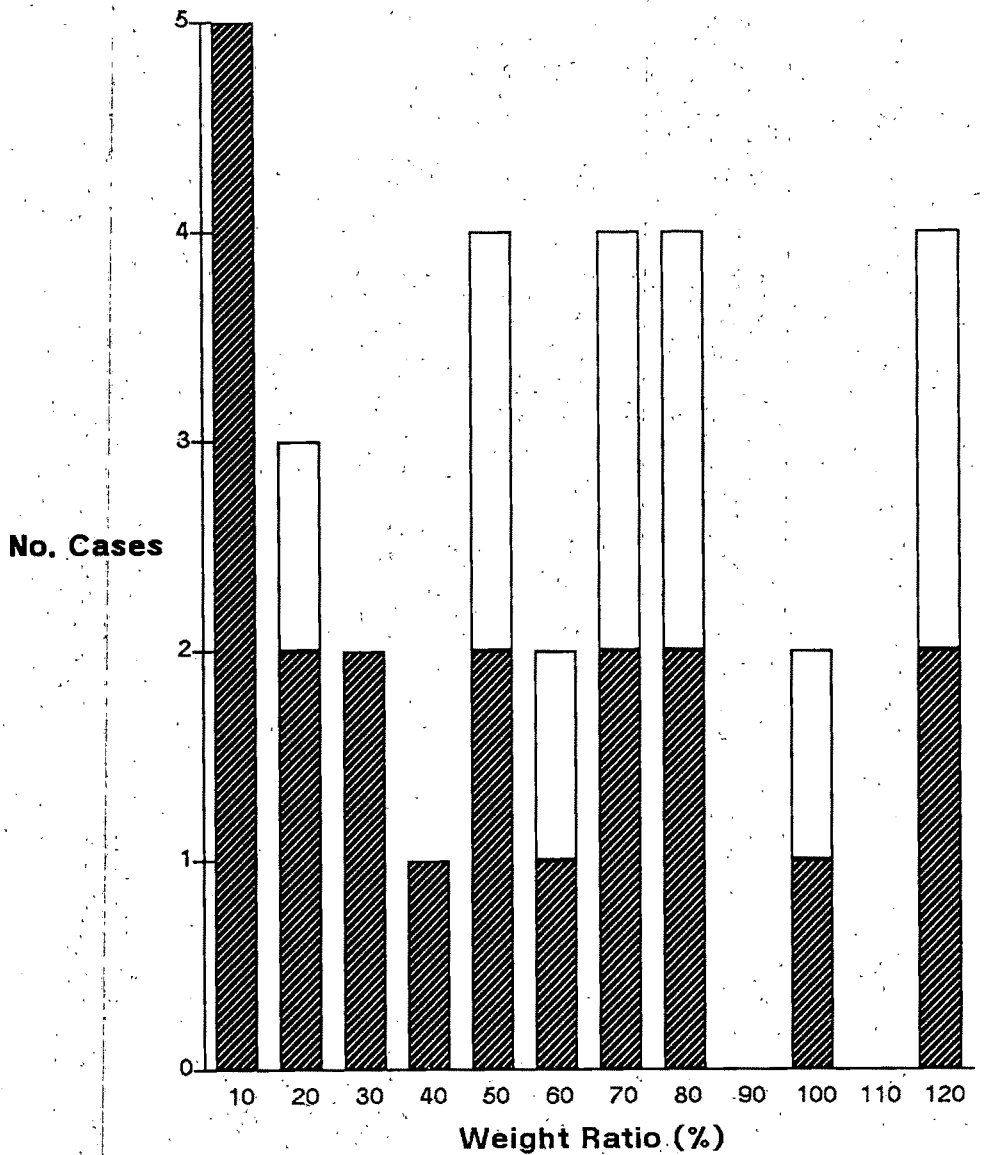

Fig. 3. Acardiac/pump-twin weight ratio and occurrence of hydramnios. Open bars are cases with hydramnios. Weight ratio is acardiac weight expressed as percentage of pump-twin weight.

Table II. Predictive value of twin-weight ratio > 50%

	*Hydramnios**	*Preterm delivery**	*Pump-twin death*
Sensitivity (%)	83	86	64
Specificity (%)	56	67	42
Positive predictive value (%)	56	71	45
Negative predictive value (%)	83	83	62

*$p < 0.05$.

Given the association of twin weight ratio and poor outcome, the problem of determining antenatally the weight of the acardiac twin was considered. The dimensions in this analysis. A second-order regression equation (Weight (gm) = $-1.66 \times$ Length $+ 1.21 \times$ Length^2) was computed and was predictive of acardiac weight with the use of its longest linear measurement ($r = 0.79$, $p < 0.001$, standard error of the estimate = 326 grams). When the actual and equation-predicted weights were compared, the mean error (±SE) in prediction was 240 ± 156 gm.

Comment

This study represents the largest single series of pregnancies complicated by acardiac twinning for which detailed perinatal outcome data are available. As such it provides a data base from which conclusions regarding outcome and the spectrum of perinatal morbidity in these pathologic pregnancies can be drawn.

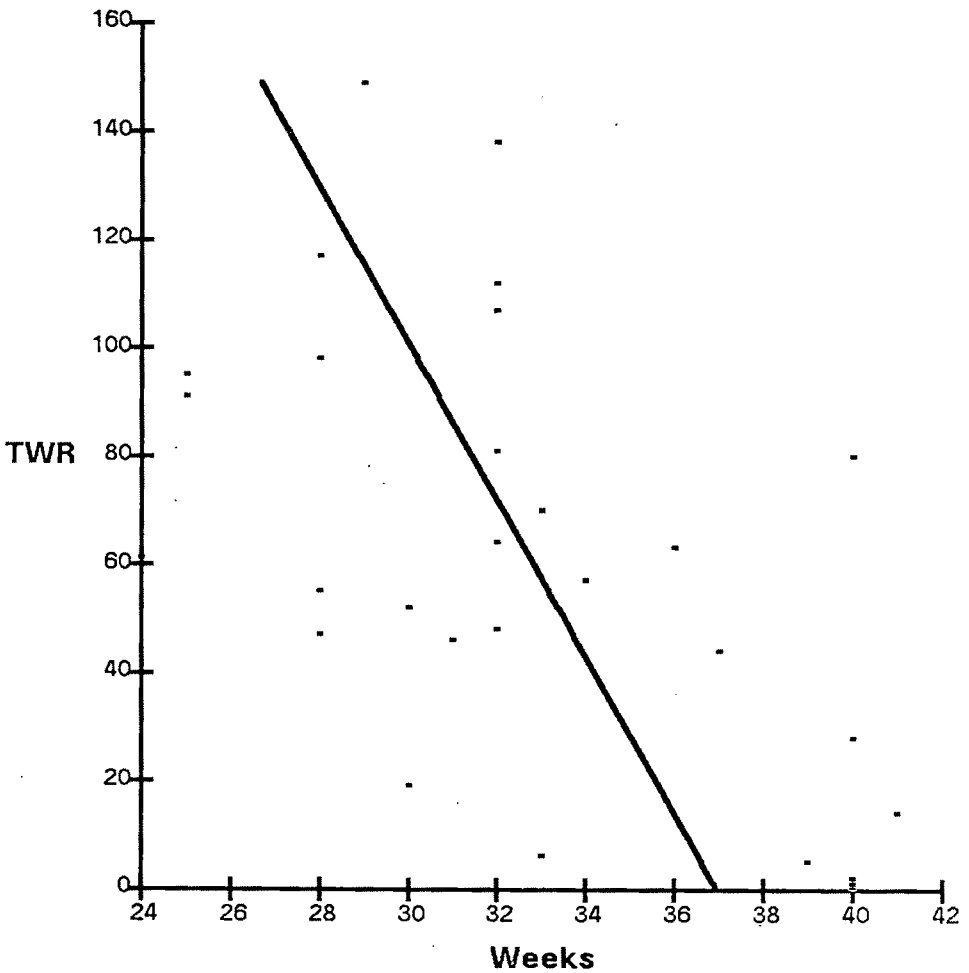

Fig. 4. Week of delivery and twin-weight ratio *(TWR). TWR* is acardiac weight expressed as percentage of pump-twin weight.

Frequently the acardiac fetus is mistaken for a twin who has died or an anencephalic fetus. The ultrasonographic features of absent head and trunk regions and increased soft tissue in the body aid in correct diagnosis.[5] Recently, pulsed Doppler examination has been used to show reversed flow through the umbilical artery of the acardiac twin.[6]

None of the acardiac pregnancies reported here underwent invasive therapies other than therapeutic amniocentesis in four cases. Thus the finding of 50% mortality provides a standard against which newer management schemes can be compared. The prominent role of hydramnios, pump-twin congestive heart failure and prematurity in the overall outcome agrees with previous reports.[6-9]

A new finding of this study was the relationship of acardiac size to pump-twin weight and its ability to predict outcome. Forecasting probable difficulties with hydramnios, preterm labor, and pump-twin cardiac decompensation may be useful in counseling patients in whom the diagnosis is made before the third trimester. Identifying a relatively small acardiac mass (<25% of normal-twin weight) may also help avoid invasive interventions such as selective hysterotomy[10] and acardiac umbilical ligation, occlusion or snaring,[7] since most of these are delivered near term.

In summary, this retrospective series suggests that half of acardiac pregnancies will result in fetal or neonatal death. Only a qurater can be expected to be delivered after 36 weeks. Preterm delivery and the attendant long-term morbidities can be expected for the remaining quarter. Innovations in management, pharmacologic treatment of the pump twin, or surgical interruption of acardiac umbilical flow may alter the prognosis in selective cases.

Embryofetal effects of pentamidine isethionate administered to pregnant Sprague-Dawley rats

Timothy W. Harstad, MD, Bertis B. Little, PhD, Roger E. Bawdon, PhD, Kraig Knoll, BS, Daniel Roe, BS, and Larry C. Gilstrap III, MD

Dallas, Texas

The effects of pentamidine isethionate on the developing embryo and fetus have not been previously published. Pregnant Sprague-Dawley rats were given various doses of pentamidine during the period of embryogenesis. Animals were killed on days 18 to 20 of pregnancy and their fetuses were removed by hysterectomy. Autopsies were performed on all fetuses. There were significant differences among groups with regard to maternal weight gain and pregnancy resorption. More pregnancy resorptions were noted in the group that received normal human doses (4 mg/kg/day) of pentamidine than in the control group ($p < 0.05$). One structural anomaly consisting of unilateral renal agenesis was noted in the 711 fetuses examined. Skeletal survey of fetal rats was unremarkable. Pentamidine was without teratogenic effects in rats when administered in doses similar to those recommended for adult humans; however, it appears to have an embryocidal effect when given in those same doses during embryogenesis. (Am J Obstet Gynecol 1990;163:912-6.)

Key words: Pentamidine, embryotoxic, teratogen, congenital anomaly

Because pregnant women with human immunodeficiency virus infection are at risk for *Pneumocystis carinii* pneumonia, pentamidine exposure for prophylaxis or treatment may be necessary. In addition, pregnant nursing personnel may be at risk for exposure while they are caring for patients with acquired immunodeficiency symdrome.[1] Pentamidine was first discovered and used in the 1930s and 1940s as an antiprotozoal agent.[2] During the 1950s pentamidine was first used to treat *P. carinii* pneumonia.[3] The Parasitic Disease Drug Service of the Centers for Disease Control supplied investigational pentamidine for the treatment of *P. carinii* pneumonia[4, 5] in 1967, and pentamidine was the most effective drug for this pulmonary infection until 1974. Trimethoprim-sulfamethoxazole at that time demonstrated activity against *P. carinii* in laboratory animals and soon replaced pentamidine as the primary treatment for *P. carinii* pneumonia.[6] However, pentamidine continued to be used as an alternative agent in those allergic to trimethoprim-sulfamethoxazole or in those who failed to respond. In 1984 LyphoMed, Inc. (Rosemont, Ill.) received Food and Drug Administration approval to market pentamidine isethionate as Pentam 300 for treatment of *P. carinii* pneumonia.[7]

This study was undertaken to evaluate the possible

teratogenicity and embryotoxicity of pentamidine because little information is available through animal studies or human experience. Reproductive studies have not been reported in the literature or performed by the product manufacturer.[7]

Material and methods

Sprague-Dawley rats initially derived from the ARS/Sprague-Dawley colony in Madison, Wisconsin, were used. Female rats weighing 250 gm and male rats weighing 300 gm were purchased and permitted to acclimate for 1 week after arrival. The rats were housed in controlled lighting (lights on between 6 AM and 6 PM) and temperature (24° to 26° C) conditions. Laboratory chow and tap water were freely available. Four to five rats were housed per cage. The animals were mated when the female rat was determined to be in proestrus or estrus by appropriate cytologic changes noted in the vaginal fluid.[8] Eighteen to 24 hours after the male and female rats were placed together, presence or absence of sperm was determined by evaluation of vaginal secretions under light microscopy. If sperm were present, the day of gestation was assigned as zero. As female rats demonstrated sperm positivity, they were randomly assigned to either the control group (group 1) or three different pentamidine groups: 4 mg/kg/day on days 6 through 11 (group 2), 20 mg/kg/day on days 6 through 8 (group 3), or 20 mg/kg/day on days 9 through 11 (group 4) (Table I). The treatment periods were chosen on the basis of implantation of the blastocyst (day 6) and early organogenesis (days 7 through 11).[8] Pentamidine (Pentam 300,2 mg/ml) was administered via tail vein injection. In a previous experiment (unpublished observations) 40% of pregnant rats died after tail vein injection of 40 mg/kg of pentamidine. In light of these data the high-dose groups in this study were chosen to receive 20 mg/kg/day (groups 3 and 4). The control group received the same volume of saline solution only as group 2. The accepted adult human dose of pentamidine is 4 mg/kg/day.

During pregnancy the rats were handled only for dosing and daily weighing. On days 18 to 20 of pregnancy (normal gestation, 20 to 22 days), the dams were killed either by guillotine or with ether, and cesarean section was performed immediately. Blood was obtained from randomly selected animals in each group for hematocrit and blood glucose determination (Table II). The fetuses were counted and the uteri were examined for evidence of embryo resorption. The fetuses were immediately placed in 10% formalin.

A skeletal survey of posteroanterior and lateral views of each fetus was performed. A xeroradiographic technique was used with selenium plates and power settings for the posteroanterior view of 120 mA at 40 to 45 kilovolt peak and 100 mA at 40 kV(p) for the lateral views. Films were evaluated for cranial, rib, vertebral, or long bone abnormalities.

After a thorough external examination of the fetuses, autopsies were performed under the magnification of a dissecting microscope. Autopsies included visualization and evaluation of palate, heart and major vessels, lungs, liver, kidneys, ureters, and bladder. Statistical analysis included the use of χ^2, Student t test, and analysis of variance.

Results

In this study 711 fetal rats were evaluated. The detailed external examinations revealed no obvious neural tube defects, limb reduction deformities, or anterior

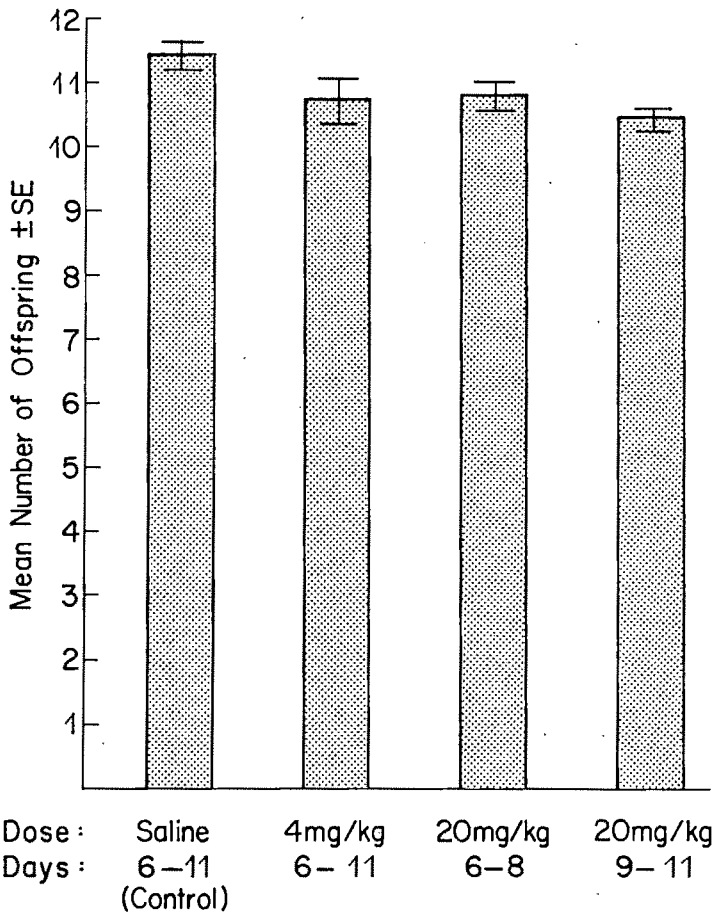

Fig. 1. Mean (± SE) number of offspring per litter. Control versus pentamidine treatment groups.

abdominal wall adnormalities. The necropsy of fetal rats revealed no detectable major anomalies except for one case of unilateral renal agenesis in group 2. Skeletal surveys of the fetal rats were unremarkable with regard to vertebral column, ribs, or long bone deformities. Comparison between groups revealed more resorptions in group 2 ($n = 26$) than in the control group ($n = 14$); this difference was significant ($p = 0.02$) (Table I). Litter size was not significantly different between the groups (Fig. 1). Other differences between groups included dam weight gain (Fig. 2). The weight at death in the control group was significantly greater than in group 4 ($p = 0.038$). Three other dams in groups 3 and 4 developed severe constipation with obvious fecal impaction at death.

During the experiment complications encountered with the administration of pentamidine included deaths of three dams that received higher doses of pentamidine. Death was preceded by lethargy, unresponsiveness, and faintly palpable heartbeat. These observations are consistent with those effects of pentamidine in rats as reported by Bielenberg and Krieglstein.[9] Pentamidine appears to have not only a peripheral hypotensive action but also a cardiac effect, including decreased heart rate and myocardial contractility.[9] Death has been reported in humans as a complication of pentamidine therapy.[8] Systemic complications with pentamidine administration were not noted in the dams in group 2 (dose of 4 mg/kg/day).

It has been reported that pentamidine may be toxic to rat islet cells in vivo and in vitro.[10] However, the mesylate salt as opposed to the isethionate salt was noted to be more potent in suppression of beta cell function. In addition to β-cell toxicity, pentamidine, through the possible mechanism of dihydrofolate reductase inhibition, may cause anemia. Blood glucose and hematocrit values obtained at death from randomly selected subjects from each group were not significantly different between groups (Table II). Whether these measurements are a sensitive indication of toxicity is unknown; histologic examination of the pancreata was not done.

Comment

Pentamidine [4,4'-diaminodiphenoxypentane di-(β-hydroxyethansulfonate)] is structurally related to guanidine. Pentamidine is made available as the isethionate salt and is active against the protozoan par-

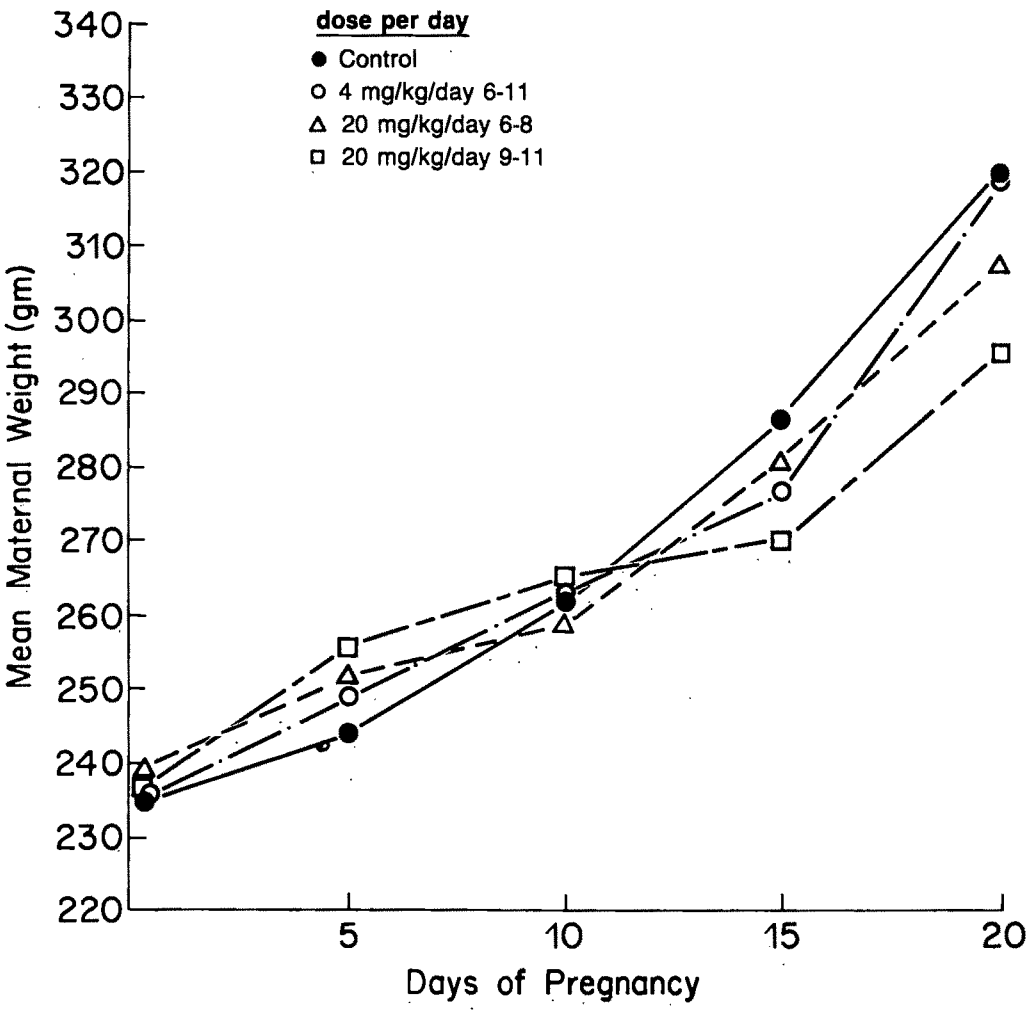

Fig. 2. Mean maternal weight versus day of pregnancy for three treatment groups and control group.

asite *P. carinii*.[2] The mechanism of action for pentamidine has been proposed to include inhibition of dihydrofolate reductase, interference with aerobic glycolysis, or inhibition of oxidative phosphorylation and nucleic acid synthesis.[11]

Pharmacokinetically, pentamidine has been studied in mice,[12] rats,[13] and humans with malignant disease[12] and acquired immunodeficiency syndrome.[14] In mice, peak levels after peritoneal injection were noted in kidneys, with next highest levels in the liver. No pentamidine was found in brain tissue. Excretion occurred primarily through the kidneys and to a smaller degree through the gut; in both routes the drug was unchanged.[15] In rat studies similar distribution of the drug was noted with parenteral administration. However, much lower systemic levels were noted with the aerosolized route.[13] In humans a parenteral dose of 4 mg/kg/day given for 12 days resulted in peak plasma values at 1 hour after injection. A mean of 17% of the 4 mg/kg dose was excreted unchanged in the 24-hour period after administration. Drug could be detected unchanged in urine at 8 weeks after treatment ceased.[12]

Pentamidine has been reported to cross the human placenta as determined in the in vitro explanted perfused human cotyledon in low concentration.[15] In our experience pentamidine administered to dams on day 18 of gestation (40 mg/kg) revealed a maternal/fetal gradient of 18:1 at 8 hours after injection as detected by high-pressure liquid chromatography[15] (maternal serum, 5.6 μg/ml; placenta, 0.94 μg/gm; fetal liver, 0.32 μg/gm), indicating fetal exposure similar to that in the in vitro human placenta (unpublished observations).

Pentamidine was not teratogenic in the rat model we used. However, there were more pregnancy resorptions in the group that received normal human doses of pentamidine on days 6 through 11 of gestation. It is conceivable that some early embryo losses may be related to malformations that were lethal to the conceptus. Although higher doses of pentamidine (20 mg/kg/day) were administered at critical times during gestation, these were for a shorter duration and were not asso-

ciated with higher resorption rates. It would thus appear that lower doses of sustained administration of pentamidine may have ill effects, possibly because of slow excretion rates and tissue accumulation.

The results of this study suggest that pentamidine has an embryocidal effect when administered parenterally over a sustained period of time. Lower tissue levels may be achieved with aerosolized administration.[18]

An evaluation of the chorionic villus sampling learning curve

Richard K. Silver, MD, Scott N. MacGregor, DO, John S. Sholl, MD, Edward D. Hobart, and Jody K. Waldee, RN

Evanston, Illinois

Prior studies have identified a correlation between the rate of fetal loss (subsequent to chorionic villus sampling) and the operators's level of experience. However, centers performing only modest numbers of procedures during the initial phase of their programs have reported loss rates similar to those of the more active diagnostic units. Our personal experience would suggest that a "learning curve" for chorionic villus sampling does exist but that fetal loss may be an insensitive end point with which to evaluate the impact of cumulative performance. In an attempt to quantify the learning curve that we have appreciated subjectively, a detailed analysis of our initial experience with chorionic villus sampling was undertaken. Between May 1988 and August 1989, a total of 185 procedures were accomplished consecutively by one operator and form the basis for this analysis. Transcervical (n = 82) and transabdominal (n = 103) techniques were used for posterior and anterior-fundal placental locations, respectively. Three pregnancy losses occurred and insufficient material for analysis was retrieved in five patients. We observed a significant reduction in the required number of placental aspirations during the study interval ($p < 0.001$). When analyzed separately, consecutive performances of the transabdominal technique demonstrated a significant reduction in the mean number of placental passes ($p < 0.00001$) along with more efficient sampling (increased sample weight/aspiration attempt; $p < 0.01$). Although the fetal loss rate is a critical measure of safety and may directly be related to operator experience, other measures of expertise (e.g., single-pass success rate) may be more appropriate indicators of competence and may be useful to centers wishing to initiate their own chorionic villus sampling programs. (Am J Obstet Gynecol 1990;163:917-22.)

Key words: Chorionic villus sampling, learning curve, transcervical, transabdominal

The current trend in prenatal diagnosis appears to favor an increased application of first-trimester procedures, including early amniocentesis and chorionic villus sampling (CVS). As the demand for CVS grows, more perinatal centers will undoubtedly offer this alternative procedure. Prior studies have identified a correlation between the rate of fetal loss after CVS and the operator's level of experience.[1-3] Other centers performing fewer procedures have reported fetal loss rates similar to those of the more active and established diagnostic units.[4, 5] The multiinstitutional CVS trial reported by Rhoads et al.[6] did not directly address the impact of operator expertise but did identify an increased fetal loss rate among patients requiring multiple placental aspirations. Inasmuch as that study relied exclusively on transcervical sampling, fundal placentation (rather than inexperience) may have been partly responsible for the increased number of sampling attempts and corresponding pregnancy losses.

6/6/22600

Since beginning our CVS program, we have appreciated a subjective "learning curve," despite the fact that our initial and subsequent loss rates have been low. Unlike most other centers, we have used both transcervical and transabdominal sampling from the inception of our program, selecting the preferred approach on the basis of placental location.[7] It is our impression that the fetal loss rate may be an insensitive end point with which to evaluate the impact of cumulative performance. Moreover, since the absolute number of fetal losses in any center's initial experience is small,[4] it is difficult to avoid a type II statistical error in analyzing any correlation with pregnancy outcome.

To identify objective evidence of the CVS learning curve that has been appreciated subjectively, we undertook a detailed evaluation of a single operator's initial experience with both transabdominal and transcervical techniques. With this analysis we hoped to estimate the number of procedures required to achieve competence or at least identify indicators of operator improvement over time. These indicators could then be used prospectively by centers wishing to develop and monitor their CVS programs.

Material and methods

The 185 cases in this study represent a subset of the 252 CVS procedures performed during the initial 16

months of our program (May 1988 to August 1989). These cases were selected for analysis because they were performed consecutively by a single operator. Twin samplings ($N = 10$ sets) and the concurrent cases of a second operator ($N = 47$) were excluded. Procedures were performed between 8 and 12 weeks' gestation. Informed consent was obtained in all instances and emphasized the concept that selection of either the transabdominal or transcervical approach was primarily dependent on placental location. This protocol was approved by the institutional review board of the hospital.

Transcervical sampling was used in those patients with either low placental implantation (directly covering the internal cervical os) or posterior placental location. In contrast, transabdominal CVS was used in those patients with either an anterior or a fundal placenta. Uterine position and maternal factors (e.g., obesity) were also considered when selecting the sampling method. Simultaneous ultrasound imaging was provided by a 3.5 MHz sector transducer (Ultramark 4, Advanced Technology Laboratories, Inc., Bothell, Wash.). A self-assembled 5.8 Fr, 27 cm polyethylene catheter (Cook Urological Inc., Spencer, Ind.) was used in all transcervical procedures. If required, a new catheter was used for each placental pass. A coaxial needle system was used in transabdominal procedures, consisting of an 18-gauge, 15 cm, thin-walled outer guide needle and a 20-gauge, 20 cm sampling needle. Thirty milliliter syringes were used for both procedures and up to three placental aspirations were allowed per patient. The sampling objective was to obtain adequate tissue (≥10 mg) for both direct preparation and culture, but the decision to attempt repeat aspirations (if a lesser sample was obtained) was at the discretion of the operator. The cytogeneticist verified the presence of villus tissue and estimated sample weight on the basis of established photographic standards.

Patient follow-up included phone contact within 1 week of the procedure, repeat ultrasound evaluation in the midtrimester, and written confirmation of pregnancy outcome by the referring obstetrician.

Statistical analysis of the data was accomplished by means of analysis of variance for continuous measures along with χ^2 (2×2 comparisons) and contingency tables (multiple column-row comparisons) for discrete parameters. Significance was considered at $p < 0.05$.

Results

To appreciate trends over the 16-month study period, patients were grouped into 4-month subsets. Selected patient characteristics during the study intervals are shown in Table I. A history of one or more spontaneous losses was common (29.7%) as was bleeding in the first trimester (20%). All patients meeting gestational age criteria underwent sampling with the exception of those patients who were first seen with either a nonviable pregnancy or active bleeding on the scheduled day of testing. Initially, transcervical CVS was used most often but was replaced by more frequent transabdominal procedures in the later months of the study (Table II; $p < 0.001$). Because there was no difference in the distribution of placental location or uterine position over time, this finding most likely represents development of operator preference for transabdominal CVS in those cases accessible by either route of sampling.

Procedure-related variables that may be representative of enhanced expertise over time are shown in Table II. A decline in the required number of placental aspirations was observed, such that 88% of all patients required only a single pass by the last 4-month interval (Fig. 1). A parallel decline in the proportion of patients requiring three samplings was also observed (16/48 between May and August 1988 vs 0/41 between May and August 1989; $p < 0.001$). A trend of decreasing aggregate sample weight was noted ($p = 0.057$), but no difference in the sample weight per aspiration attempt was seen. Inability to obtain a sample was uncommon (5 of 185 patients).

These same procedure-related variables were analyzed separately for the transcervical and transabdominal subsets (Tables III and IV). In transcervical subsets

successful sampling was accomplished with a single pass in 11 of 12 patients during the final four-month period compared to 17 of 34 patients in the initial four-month period. Improvement in the transabdominal technique over time was represented by a significant reduction in the number of required sampling attempts, as well as a significant increase in the amount of villi retrieved per placental aspiration.

Three fetal losses occurred (before 20 weeks' gestation; patients 10, 62, and 64). Although it is notable that these fetal losses occurred "early" in the study (during the first 5 months), the significance of this observation is unclear. In an attempt to identify lesser morbidities that might also relate to proficiency in sampling, we analyzed the incidence of postprocedure bleeding (within 48 hours) over the duration of the study (Fig. 2). A nonsignificant trend toward a reduction in this complication was observed; however, most bleeding was associated with the transcervical technique (11 of 15 patients), and 10 of these patients also had a history of bleeding before the procedure.

Comment

During the initial 16 months of this experience with CVS, we observed trends that support the concept of a learning curve. Specifically, fewer placental aspirations were required overall; a larger sample size and more effective sampling was noted with the transabdominal technique and less postprocedure bleeding was reported among the transcervical procedure subset. The low rate of fetal loss during the entire study interval, although encouraging, belied the fact that improvement in technique and efficiency was still taking place. Unlike other centers that have reported an ex-

tensive "preparatory experience" with pregnancies scheduled for elective termination,[4, 5] fewer than 20 cases were logged in our center before CVS was performed on continuing pregnancies (primarily because of limited local availability of termination services).

Our study was restricted to the experience of a single operator so that we might accurately represent the learning curve for an individual, since it is likely to be different from one operator to another. Differences in expertise among centers has also been alluded to both by the variation in reported fetal loss rates[8] and recently by a wide range (among seven centers) in the proportion of cases requiring multiple placental passes (7% to 45%).[6] The second operator in our center has also experienced a learning curve, although fewer cases have been required to reach a consistent (>90%) single-pass rate. This may relate to a prior extensive experience with ultrasound-guided perinatal procedures.[9] As an extension of these observations, it may be appropriate to have only one operator at a time learn these techniques, especially if a limited initial caseload is anticipated.

When CVS was initiated in our center, we were not committed to either the transcervical or transabdominal approach. However, our preparatory experience suggested that posterior or low implantations were most easily sampled transcervically, whereas fundal and anterior placentas were more amenable to transabdominal aspiration. During the latter portion of this study, those cases amenable to either approach were most

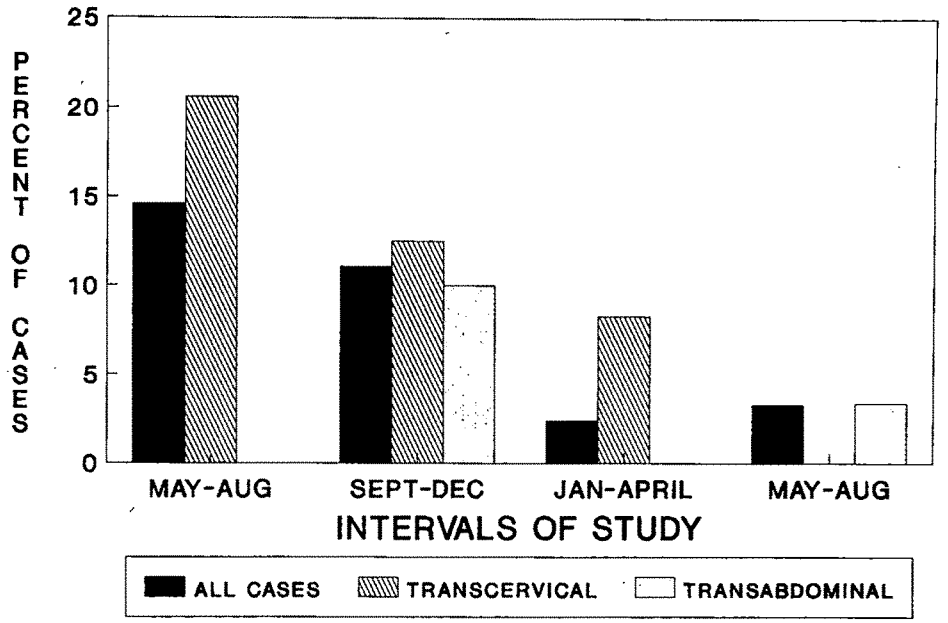

Fig. 2. Incidence of postprocedure bleeding (within 48 hours) compared by route of sampling and correlated with increasing experience during study intervals ($p = 0.07$). Bleeding did not occur during interval if subgroup is not represented by *shaded bar*.

often sampled transabdominally. This shift favoring transabdominal procedures likely contributed to the temporal improvement observed (Table IV). The virtues of transabdominal sampling have been identified by others[10, 11] and include avoidance of cervicovaginal bacteria and less frequent postprocedure bleeding. However, until a properly controlled trial (which includes placental location and uterine anatomy as independent variables) identifies a safer approach, we believe that both procedures should be learned and used.

Obstetricians are generally familiar with percutaneous procedures and experience with ultrasonographic guidance should provide an additional advantage in learning transabdominal CVS. It is therefore interesting that more dramatic improvements seemed to occur when the transabdominal procedure was performed in this series. We would suggest that whether a single or coaxial needle system is used matters less than the angle with which the chorion frondosum is entered.[11, 12] Entry parallel to the long axis of the placenta is of great importance to both the success of the sampling and the amount of tissue retrieved, especially when a small-gauge needle is used. These nuances in transabdominal technique probably contributed most to the learning curve we observed.

Review of these data has not identified an obvious "break point" beyond which CVS competence was achieved. A more sophisticated analysis, combining various end points indicative of expertise, would only serve to characterize the experience of a single physician. Instead factors such as a minimum "single-pass success rate" should probably be emphasized.[6] This is likely to vary somewhat, depending on inherent operator skill and prior experience. It is reassuring to note that during our acquisition of expertise and that of others[4] an increase in fetal loss rate was not realized. Hopefully this pattern will continue as more perinatologists offer these services to their patients.

The association of single umbilical artery with cytogenetically abnormal pregnancies

Devereux N. Saller, Jr., MD, Carol Lynn Keene, MD, Chen-Chih J. Sun, MD, and Stuart Schwartz, PhD

Baltimore, Maryland

The clinical significance of the absence of one of the two umbilical arteries (single umbilical artery) lies in its association with congenital malformations. Whether this association includes cytogenetic abnormalities is less clear. A retrospective review of all detected chromosomally abnormal pregnancies at the University of Maryland was carried out. Of 109 cytogenetically abnormal pregnancies, the number of umbilical cord vessels could be documented in 53 cases. Six (11.3%) had a single umbilical artery. A single umbilical artery was noted in two of nine fetuses (22.2%) with trisomy 18 and in two of six fetuses (33.3%) with trisomy 13. Two other unusual chromosomal constitutions were noted in cases of a single umbilical artery. None of the 11 fetuses with sex chromosome abnormalities (including eight with monosomy X) had a single umbilical artery. Of 18 fetuses with trisomy 21, none had a single umbilical artery. This study suggests that a single umbilical artery is preferentially associated with certain karyotypic abnormalities and that trisomy 21 does not appear to be associated with a single umbilical artery. (AM J OBSTET GYNECOL 1990;163:922-5.)

Key words: Single umbilical artery, chromosome abnormality, trisomy

A normal umbilical cord contains a single vein and two arteries surrounded by Wharton's jelly. It has been recognized for centuries that on occasion abnormalities of the umbilical cord may be seen. One of the most common of these abnormalities with clinical significance is that of a single umbilical artery. A single umbilical artery represents the absence of the second umbilical artery and its importance has been discussed for many years. The first recorded accounts of a single umbilical artery date from the 1500s.[1] The first account in the American literature is in 1908.[2] The clinical significance of a single umbilical artery lies in its association with congenital malformations. A variety of malformations have been associated with a single umbilical artery, including cardiovascular malformations, central nervous system defects, gastrointestinal defects, musculoskeletal malformations, and urogenital defects.[1, 3, 4]

Much of the literature on single umbilical artery predates the clinical use of chromosome analysis, and it is difficult to find information concerning the association of a single umbilical artery with chromosomal abnormalities in the literature.[4] Several of the early descriptions of autosomal trisomies describe a single umbilical artery as an occasional feature in anecdotal cases; however, precise incidences are not available.[5]

Material and methods

In an effort to delineate a possible association between the presence of a single umbilical artery and aneuploidy, a retrospective study of all cytogenetically abnormal pregnancies or deliveries was carried out.

These pregnancies were ascertained through the cytogenetic laboratory at the University of Maryland Hospital. All abnormal karyotypes obtained between 1982 and May 1989 were evaluated. Cases included for evaluation were both amniocentesis specimens and tissue culture specimens (of second- and third-trimester pregnancies). Because of the lack of available information or appropriateness, cases excluded from further evaluation were those with aneuploidy identified from any first-trimester specimens (such as abortus material and chorionic villus samples), anembryonic molar pregnancies, and neonatal blood and bone marrow specimens. Both laboratory and clinical records were reviewed in an effort to find descriptions of the types of anatomic changes that were associated with the cytogenetic abnormality, as well as pathologic conditions in the placenta or autopsy documentation of pathologic conditions in the placenta and umbilical cord. Records from several hospitals were obtained. All records were reviewed by D. N. S.

Results

Data from amniocentesis and tissue culture specimens were initially evaluated separately because of inherent differences between the groups in gestational age and severity of morphologic abnormalities.

A total of 80 amniocentesis specimens were ascertained with abnormal karyotypes. These were mainly second-trimester gestations (75 of the 80 cases), most of which were first seen because of an indication of advanced maternal age (55 of the 80 cases). Although sonographically detected morphologic abnormalities were noted in several instances, this was the initial indication for amniocentesis in only 15 of the 80 cases. None of the patients carried the prenatal diagnosis of a single umbilical artery, and therefore awareness of its presence was not an indication for amniocentesis and did not affect clinical management in any instance. Of the 80 karyotypically abnormal amniocentesis specimens, pathologic follow-up could be obtained in only 36 cases. Documentation of the pathologic status of the remaining 44 cases was unattainable for one of several reasons. Four patients carried the pregnancy to term despite the knowledge of aneuploidy. The records from the referring institution where the specimen originated were not available in 27 cases. The pathology report did not comment on the number of umbilical vessels in nine cases (six of which were specimens from dilatation and evacuation procedures). One patient refused autopsy examination and three in-house charts were unavailable. The 36 cases with pathologic documentation included 13 with trisomy 21, seven with trisomy 18, four with trisomy 13, four with monosomy X, and eight with unusual karyotypes listed in Table I. In 33 of these 36 cases the gestational age was 28 weeks or less. Of these 36 cases, five had a single umbilical artery. These included two with trisomy 18 (out of seven in which follow-up was obtained) and one with trisomy 13 (out of four in which follow-up was obtained). Additionally there were two single umbilical arteries noted in unusual cytogenetic abnormalities—a deletion of the short arm of chromosome 5 [46,XX,del(5)(qter→p14:)] and a case of trisomy 9 mosaicism [46,XX/47,XX+9].

Table I. Amniocentesis

Triploidy	0	—	—
Monosomy X	4	0	0
Other sex*	3	0	0
Other†	5	2	40
Total	36	5	13.9

*Other sex karyotypes included: 47,XXX; 47,XXY; 45,X/46, X+mar.

†Other karyotypes included: 46,XX,del (5) (qter→p14:)
46,XX/47,XX+9
46,XY,17q+
46,XX,inv(1)(p21p36),del(1)(p22.1→p22.3?)
46,XX,t(1;19)(p11;p11)/47,XX,t(1;19)(p11;p11)+der(1)t(1;19)(p11;p11)

Twenty-nine other patients, after being informed of the presence of an ultrasonographically detected morphologic abnormality or a fetal death, declined prenatal diagnosis of karyotype. In these cases fetal tissues or placental villi were obtained at the time of discontinuation of the pregnancy and sent to the cytogenetic laboratory for karyotyping. This group included a wider range of gestational ages but mainly pregnancies in the second trimester (15 of 29 cases at ≤28 weeks). All patients in this group, for whom termination of pregnancy was an available option, proceeded with termination. This group included nine cases of fetal death and five sonographically detected morphologic abnormalities at or near term. Of these 29 specimens, pathologic follow-up could be obtained in 17 cases (12 of which were ≤28 weeks' gestation). The 12 cases without pathologic follow-up included nine in which the charts were not available at the referring institutions and three in which the charts were not available within the University Hospital. These 17 cases included five with trisomy 21, two with trisomy 18, two with trisomy 13, four with triploidy, and four with monosomy X (Table II). Of these 17 cases, only one (with trisomy 13) was noted to have a single umbilical artery.

In total, 109 aneuploid pregnancies were identified and complete pathologic follow-up was obtained in 53 (48.6%). Of these 53 cases, six (11.3%) were associated

46,XX/47,XX,+9	1

with a single umbilical artery (Table III). If the data from trisomy 13 and trisomy 18 pregnancies are combined, 4 of 15 pregnancies (26.7%) demonstrated a single umbilical artery. This, when compared with 0 of 18 trisomy 21 pregnancies demonstrating a single umbilical artery, reaches statistical significance (two-tailed Fisher's exact test, $p = 0.033$).

Comment

Single umbilical artery is a relatively common congenital malformation the incidence of which ranges between 0.08% and 1.9% with a mean of 0.63%.[1] Data obtained from live births show a lower incidence than those obtained from stillbirths, and the incidence of a single umbilical artery in first- and second-trimester fetuses is still higher, ranging from 0.2% to 9.68%.[1, 4] Other factors that have been associated with an increased incidence of a single umbilical artery in addition to congenital malformations include white race and low birth weight.[1, 6] Multiple gestation, especially with discordance in weight, has also been associated with a single umbilical artery.[1, 7]

It has been suggested that a single umbilical artery is associated with cytogenetic abnormalities and with congenital malformations in general.[4] Data supporting this are difficult to find and specific associations with individual chromosome abnormalities are not well documented in the literature. A single umbilical artery has been found in 10% to 50% of infants with trisomy 18.[8] Smith[5] suggested that single umbilical artery is on occasion associated with trisomy 13. In a report of 107 fetuses with central nervous system malformations, 20 (18%) had a single umbilical artery.[9] Fifteen of these 20 were karyotyped and eight (53%) were aneuploid (trisomy 13 or trisomy 18). Of karyotyped fetuses without a single umbilical artery in this same series, 11 of 45 (24%) were aneuploid. To our knowledge there are no other reports (other than anecdotal case reports) of any other chromosomal abnormalities (including trisomy 21) in association with a single umbilical artery. In this small retrospective study, out of a total of 109 cytogenetically abnormal pregnancies, pathologic data could be obtained in 53 cases. A total of six pregnancies were noted to have a single umbilical artery. This gives an incidence of 11.3% for single umbilical arteries among cytogenetically abnormal pregnancies in general. Additionally it appears that specific cytogenetic abnormalities are associated with a single umbilical artery. Of the six cases of single umbilical artery found, two were in cases of trisomy 18 (two of nine, 22.2%) and two were in cases of trisomy 13 (two of six, 33.3%). It is difficult to interpret the significance of the other two cases with a single umbilical artery (46,XX/47,XX+9; 46,XX,5p−).

In this series there is no association of a single umbilical artery with trisomy 21. Of 18 cases of trisomy 21 in which pathologic follow-up data were obtained, none demonstrated a single umbilical artery. The data from trisomy 13 and trisomy 18 pregnancies, (four single umbilical arteries in 15 pregnancies) when compared with trisomy 21 pregnancies (no single umbilical arteries in 18 cases), reaches statistical significance (two-tailed Fisher's exact test, $p = 0.033$). Additionally there was no evidence of a single umbilical artery in 11 cases of sex chromosome abnormalities (including eight cases of monosomy X).

It is noteworthy that there was no apparent association in this series of a single umbilical artery with any other specific morphologic abnormality. It could be theorized that a single umbilical artery is a vascular anomaly and therefore might have an association with congenital heart defects. The pathologic examination of those fetuses with a single umbilical artery included a thorough internal dissection in only three cases, but in two of the three cases the single umbilical artery was noted in the presence of an anatomically normal fetal heart. This suggests that a single umbilical artery is at least not a direct sequela of congenital heart defects.

Single umbilical artery is a congenital malformation that appears to provide information and may help in differentiating between certain cytogenetic abnormalities. Medical professionals may not take note of it at the present time. This is well demonstrated by the inability to document the number of umbilical arteries in our attempts to obtain pathologic and clinical follow-up on these cytogenetically abnormal pregnancies. Observation of the number of umbilical arteries is something that can be done on gross examination and this

noninvasive information can be obtained at little or no cost after delivery of the pregnancy.

Before delivery the number of umbilical vessels may be able to be ascertained by ultrasonographic examination.[9-12] The incidence of aneuploidy when a single umbilical artery is noted prenatally remains unknown. The identification of a single umbilical artery in the presence of a central nervous system malformation is suggestive of aneuploidy (trisomy 13 or trisomy 18).[9] Therefore, when congenital malformations are noted on ultrasonographic examination prenatally, discerning the number of umbilical vessels may be possible and may be useful in suggesting specific cytogenetic diagnoses. For example, in the case of a congenital heart defect or in the case of a cystic hygroma, finding two umbilical vessels would appear to lead one away from trisomy 21 or monosomy X as a cytogenetic diagnosis and toward trisomy 13 or trisomy 18 as possible diagnoses.

The presence of a single umbilical artery is associated with anatomic and karyotypic abnormalities. It is information that is easily obtained at delivery and may be noted prenatally on sonographic examination. The documentation of this information in the clinical record would therefore seem warranted.

We thank Dr. Donald R. Coustan, Shirley Belschner, and Elizabeth Da Fonseca for their assistance in the preparation of this manuscript.

Transcervical chorionic villus sampling and amniocentesis: A comparison of reliability, culture findings, and fetal outcome

J. E. Ferguson II, MD, Dan J. Vick, BA, Joan S. Hogge, MS, and W. Allen Hogge, MD
Charlottesville, Virginia

We evaluated the reliability, culture findings, and fetal outcome after transcervical chorionic villus sampling or amniocentesis in a group of 860 patients. All procedures were performed for the indication of advanced maternal age with consistent procedure and laboratory techniques. Successful procedures were completed in 97.7% (420/430) of patients in the chorionic villus sampling group, compared with 99.5% (428/430) in the amniocentesis group ($p < 0.01$). Success was more frequent with only one attempt in the amniocentesis group (427/428) versus 354 of 420 in the chorionic villus sampling group ($p < 0.001$). Culture failure was more common after chorionic villus sampling ($p < 0.001$). Pregnancy loss rates through 28 weeks' gestation and the entire gestation were not significantly different. The prevalence of preterm delivery did not vary between groups, but birth weights of infants in the chorionic villus sampling group were significantly greater. In summary, the present investigation supports previous findings that chorionic villus sampling is a safe alternative to amniocentesis and is not associated with long-term pregnancy complications. (Am J Obstet Gynecol 1990;163:926-31.)

Key words: Transcervical chorionic villus sampling, amniocentesis, prenatal diagnosis

Transcervical chorionic villus sampling (CVS) is a relatively new addition to the armamentarium of prenatal diagnostic techniques; consequently questions remain concerning its reliability and safety.[1-3] Recently, multiinstitutional collaborative trials have attempted to address these issues by comparing CVS with amniocentesis, but such studies suffer from differing indications for the procedures and from variability of operator experience, operative technique, and type of catheter or gauge of needle used, both within and between institutions.[4, 5] In an attempt to overcome these potentially confounding variables, we compared the outcome of pregnancies in which chorionic villus sampling or amniocentesis was performed by only two persons at a single institution with consistent procedure and laboratory techniques for the sole indication of advanced maternal age. In addition, the efficacy and accuracy of each procedure was ascertained.

Material and methods

In the Prenatal Diagnosis and Treatment Center in the Department of Obstetrics and Gynecology at the University of Virginia Health Sciences Center, transcervical CVS was performed on 669 patients between December 1986 and June 1989. Our study group comprised all patients with singleton gestations with advanced maternal age as the sole indication and whose estimated date of confinement was before July 18, 1989 ($n = 430$). The CVS program was initiated in November 1985 after approval was obtained from the Human Investigation Committee. More than 140 procedures and cytogenetic analyses were performed before the initiation of this study. Patients in whom an amniocentesis was attempted were selected for comparison with the patients undergoing CVS by review of the Center's log book of procedures and identification of the most recent 430 consecutive patients whose estimated date of confinement was on or before July 15, 1989. These patients also had singleton gestations, and their procedures were performed for the indication of advanced maternal age. Physicians and laboratory personnel were likewise experienced in the performance of amniocentesis and cytogenetic analysis inasmuch as approximately 800 procedures had been completed during the year preceding the initiation of this study. The majority of the patients who were seen in the Center were referred from outside the institution and the patient and her physician, before referral and evaluation by us, had jointly decided whether CVS or amniocentesis was desired. After the diagnostic procedure was completed, management of pregnancy was at the discretion of the patient's physician.

All procedures were performed by either of two operators (W. A. H. or J. E. F.). For all patients, information concerning the pregnancy and procedure was

6/6/22345

prospectively coded on the data forms at the time of the patient visit. Gestational age was determined by a combination of the last menstrual period and standard ultrasonographic biometric parameters.[6] If the gestational age as determined by ultrasonography was discrepant by more than 1 or 2 weeks, respectively, in patients in the first or second trimester of pregnancy, then the gestational age derived by ultrasonography was used. In all instances, fractions of a week were converted to the appropriate decimal equivalent for coding.

CVS was performed on patients between 9 and 12 weeks' gestational age, as previously described.[1, 7] All samples were obtained with 16-gauge polyethylene catheters (Angiomed, West Germany). In no instance were greater than three attempts made. A new catheter was used for each attempt. The samples were immediately inspected by the operator under a dissecting microscope to determine that a sufficient amount (>10 mg) of villi had been obtained. Villi were dissected free of all maternal tissue and placed into culture.[1] "Direct" preparations of villi were performed by the method of Gibas et al.[8] but were used only for confirmation of long-term culture results.

Amniocenteses were performed under direct ultrasonographic visualization with a 22-gauge needle. The amniotic fluid cells were then cultured in standard fashion with both a cover-slip and flask method.

An attempted CVS was defined as passage of the catheter through the endocervical canal into the chorion frondosum and suction applied. An amniocentesis attempt was defined as the needle being placed through the maternal abdomen and into the uterus. For both procedures, "success" was defined as occurring if a sufficient amount of the appropriate material for culture was obtained; a "failed" procedure occurred when an attempt was made but these criteria were not met. Pregnancy follow-up information was routinely solicited for all patients by writing to their physicians. Requested data included birth weight, gestational age at delivery, infant gender, pregnancy complications, infant malformations, if present. If these questionnaires were not returned, follow-up letters were sent or phone calls were placed to physicians and patients to obtain pregnancy outcome information. A pregnancy was considered to have been terminated for patient desire if termination occurred at the patient's request without any chromosomal or other fetal abnormality. Preterm delivery was defined as delivery before 37 weeks' gestation (259 days).

Culture failure occurred when, despite obtaining a sufficient amount of the appropriate material for culture, cytogenetic analysis could not be completed. A cytogenetic abnormality was stated to exist when a deviation from normal chromosome number or morphology was identified.

Patient and procedure information was maintained on an Apple Works data base system. Statistical analysis of the data used either a Student t test, χ^2 tests (2×2 or 3×2) with Yates' continuity correction factor, or the Fisher exact test when applicable.

Results

The patient characteristics for the 860 women who met the above parameters for inclusion and had CVS or amniocentesis performed are depicted in Table I. It can be noted that the patient groups were comparable with respect to the number of live-born children, history of prior spontaneous and elective abortions, the percentage whose race was white, and the percentage who received prenatal care before the procedure. The maternal age at the time of the procedure was somewhat greater in the patients in the CVS group.

Chorionic villus sampling procedures were performed at a mean gestational age of 10.3 ± 0.7 weeks (range, 8.8 to 12.2 weeks). Amniocentesis was performed at a mean gestational age of 16.9 ± 1.4 weeks (range, 12.7 to 23.7 weeks). "Early amniocentesis" was not routinely offered during the interval encompassed in this study and only two procedures were attempted at gestational ages earlier than 14 weeks. There were 10 failed procedures in the women in the CVS group compared with two failed procedures in women in the amniocentesis group ($p < 0.05$). The two failed procedures in the amniocentesis group occurred after attempted amniocentesis at 18 and 21 weeks' gestational age, when the laboratory determined that maternal urine had been withdrawn rather than amniotic fluid. Each patient was obese and had a repeat amniocentesis without incident. The 10 failed CVS procedures occured when either no tissue or only decidua was obtained. In these 10 patients in whom CVS failed, the procedure was discontinued when it was decided tissue could not be obtained after two attempts in six cases and after only one attempt in the remaining four; in no instance were three attempts made in this group. The failed CVS procedures were distributed randomly over the interval of this study. These procedures were believed to have failed because of an inaccessable placental location in six cases, a combination of leiomyomata uteri and placental location in two cases, and difficulty caused by leiomyomata or a severely retroverted uterus in one instance each. Of these 10 patients, failed CVS procedures occurred in three before the introduction of transabdominal CVS into our program. The gestational age and reason for failure in each precluded rescheduling a later transcervical CVS attempt and they were offered and accepted midtrimester amniocentesis. In three of the remaining seven patients, placental location enabled us to offer and successfully perform transabdominal CVS. In the remaining four

*$p < 0.001$.

patients, transabdominal CVS was not offered because it was judged that the placental location would have precluded success. In two of these four patients, limitations because of gestational age did not allow a repeat attempt at a later date and they, too, were offered and accepted midtrimester amniocentesis. In the other two patients, it was believed that interval growth would allow successful repeat CVS procedures 1 week later; such was the case in each.

As can be noted in Table II of the successful amniocentesis procedures, one attempt was required to obtain sufficient material for culture in all but one patient. In the successful CVS group 61 patients (14.5%) required two attempts and five (1.2%) required three attempts. This difference was significant ($p < 0.001$).

There were no failed cultures in the 428 women in whom amniocentesis was successful as compared with 12 instances in the patients who had successful CVS procedures ($p < 0.01$). Patients in the CVS group who had failed cultures had an average of 25 mg of villi obtained (range 10 to 40 mg). In the 12 cases of failed CVS cultures, "direct" preparations of villi failed in five and were not set up in two cases. In five instances, the direct preparation revealed a normal chromosome complement and was available for reporting, but it was the policy of our Center to not report results just on the basis of the direct preparation. In addition, the occurrence of culture failure was evaluated in relationship to laboratory experience over the duration of the study. Culture failures were evenly distributed over time, and there was no indication that laboratory success improved as the study continued. Thirteen cytogenetic abnormalities (3.2%) were detected in the 408 CVS patients in whom culture was successful as compared with nine abnormalities (2.1%) in the 428 patients in the successful culture amniocentesis group (p = NS). Cytogenetic abnormalities in the CVS group included trisomy 21 ($n = 7$), trisomy 18 ($n = 3$), mosaicism ($n = 2$), and marker chromosome ($n = 1$). The mosaicism seen in the CVS culture included tetraploidy (26% of cells) and trisomy 13 (10% of cells). Seven cases of trisomy 21 and one case each of pseudomosaicism (trisomy 18 in one cell) and an unbalanced translocation were encountered in patients in the amniocentesis group. Patients in the CVS and amniocentesis group with mosaicism were further evaluated with amniocentesis or fetal blood sampling, respectively, and had normal chromosome results. Therefore these pregnancies were continued and these infants were chromosomally and phenotypically normal.

To evaluate outcome in the pregnancies that were "intended to continue," the cases that were terminated for diagnosis or request were removed from the total number of procedure attempts in each group. In the CVS group, there were 13 pregnancy terminations (11 cytogenetic abnormalities, 1 anencephaly, and 1 for apparent sex selection that was unknown to us at the time of procedure), resulting in 417 continuing pregnancies. Eight pregnancies (all cytogenetically abnormal) were terminated in the amniocentesis group, leaving 422 "intended to continue." In Table III pregnancy outcome is tabulated. Differences in pregnancy loss at gestational ages ≤28 weeks and total pregnancy loss rates were not significantly different. Of the four pregnancy losses in the amniocentesis group before 28 weeks' gestation, two were fetal deaths with associated bleeding and cramping at 20½ weeks; one was a spontaneous abortion at 19½ weeks; and one was stillborn at 26 weeks' gestation. The remaining two pregnancy losses

Table III. Pregnancy outcome

	CVS		Amniocentesis		
	No.	%	*No.*	%	*p Value*
Procedures attempted	430	—	430	—	—
Intended to continue	417	—	422	—	—
Pregnancy loss					
<28 weeks	10	2.4	4	0.9	NS
All weeks	11	2.6	6	1.4	NS
Live birth	406	—	416	—	—
Term	385	94.8	389	93.5	NS

Birth weight (gm)	3499 ± 597	—	3408 ± 654	—	<0.05

in the amniocentesis group were stillborn fetuses at 29 and 40 weeks' gestational age. In none of these losses was more than one attempt at amniocentesis required. There were 10 pregnancy losses before 28 weeks' gestation in the CVS group; all occurred before 20 weeks' gestation (range, 7 days to 10 weeks after the procedure). In the 10 pregnancy losses at <28 weeks' gestation in the CVS group, seven occurred within 3 weeks of the procedure and were associated with bleeding and cramping. Two additional patients had similar symptoms and pregnancy loss at 4 and 8 weeks after the procedures. The final patient was noted to have persistent spotting after the procedure and ultrasonography at 18 weeks' gestation documented oligohydramnios; spontaneous abortion occurred 2 weeks later. In four of the 10 patients, two attempts were required, in none was three required. The solitary loss beyond 28 weeks' gestation in the CVS group was a 34-week stillborn fetus in which a single attempt was required.

The mean maternal age, gestational age at the time of the procedure, and amount of chorionic villi sampled were not significantly different when patients with fetal losses were compared with those with no losses. In addition, there was no significant relationship between the number of CVS attempts and the risk of fetal loss.

There was no difference between procedures in the incidence of preterm deliveries. However, the mean birth weight was greater in the infants in the CVS group (3499 ± 597 gm) when compared with infants in the amniocentesis group (3408 ± 654 gm) ($p < 0.05$). There was no serious maternal morbidity in either group.

Comment

Since its introduction in the early 1970s amniocentesis, coupled with cytogenetic analysis of cells in the amniotic fluid, has been considered the standard test for prenatal diagnosis. However, the belief that amniocentesis should be considered the standard test has been questioned recently as generally reassuring information has accumulated about CVS.[9] CVS is gaining wide acceptance by patients and physicians alike because it offers the possibility for early results. However, complete information about its safety, efficacy, and accuracy is essential before CVS can be implemented on a large scale. To address these issues, several collaborative trials have been performed. The drawback of these trials was that variability existed in operator experience, as well as the procedure and laboratory techniques used.[4,5] For instance (although it is understandable because CVS was a relatively new technique at the time), in the U.S. Collaborative trial, each operator had to have completed only 10 CVS procedures and each center only 25 to begin the study.[4] In the Canadian trial, criteria for "reasonable experience" by the operator and cytogenetics laboratory were somewhat more stringent, but the CVS techniques varied from center to center, as did the cytogenetics techniques, gauge of amniocentesis needle, and use of ultrasonography during amniocentesis.[5] The experience of amniocentesis operators was not addressed in either study, and thus it is possible that amniocentesis procedures were relegated to relatively inexperienced personnel. All these factors could have unwittingly biased the comparison between CVS and amniocentesis. Our study attempted to overcome some of these potential deficiencies by selecting patients at a single center in whom the procedures were performed only for the indication of advanced maternal age by two operators who were experienced and used consistent CVS and amniocentesis techniques. Laboratory methods were well established and consistent, as well.

Our results indicate that each procedure is highly successful at obtaining the appropriate material for culture. Although amniocentesis is more likely to be successful both overall and with one attempt only, the incidence of failed CVS procedures (10/430 or 2.3%) is quite acceptable, and similar to that reported in other series.[1,10] In addition, of the patients in whom CVS failed, in all it was possible to obtain a cytogenetic di-

agnosis by offering them transabdominal CVS, amniocentesis at a later date, or by repeating the transcervical CVS procedures in 1 week. We believe these differences between the CVS and amniocentesis groups underscore the fact that CVS is inherently a somewhat more difficult procedure to perform.

Culture failure was, likewise, more common in the CVS patients compared with patients in the amniocentesis group. In most instances there was no explanation for the failed cultures, despite adequate sample size. We do not believe laboratory inexperience was responsible for the failures because at least 140 CVS cultures had been set up and evaluated before processing the villi from patients in this study. The U.S. Collaborative study and Canadian trial, likewise, noted a greater likelihood of culture failure in CVS patients.[4, 5] On the contrary, Wright et al.[11] showed tissue culture failure to be less common in CVS.

Similar to other studies[4, 11] the incidence of cytogenetic abnormalities was not significantly different when compared between groups. There were no errors in diagnosis in either group. The incidence of mosaicism was comparable in both CVS and amniocentesis. Further evaluation in all cases documented a normal fetal chromosome result and all pregnancies continued with normal outcomes.

Our data indicate that pregnancy loss rates before 28 weeks' gestation and through the entire gestation were not significantly different between the CVS group and patients in the amniocentesis group. This result is in close agreement with the U.S. Collaborative Trial.[4] Whereas this is reassuring information for us to provide to patients seen in our Center, this reassurance must be tempered somewhat because our study was not randomized and we did not evaluate all socioeconomic factors that could have possibly affected pregnancy outcome, such as level of income or education. Also, despite the fact the study encompassed 2 ½ years and 860 subjects, the power of such a conclusion is rather low (36%). It is important to remember, however, that an "uncorrected" comparison of pregnancy outcome such as we report does not take into account the well-known fact that there is a background rate of loss between the 9 to 12-week interval of pregnancy and the 16 to 18-week interval. Because we did not see patients undergoing amniocentesis before referral, they could not be evaluated during weeks 9 to 12 of pregnancy to establish the pregnancy loss rate between that interval of gestation and when amniocentesis was undertaken. However, by combining the data in this study with that from the U.S. Collaborative Study, we can more realistically estimate the risk of CVS compared with amniocentesis. From the latter study information on the approximate pregnancy loss rate between 9 and 16 weeks' gestation is available; after a normal ultrasonographic examination at 9 to 12 postmenstrual weeks, 2.5% of the pregnancies were lost before a 16-week evaluation.[4] With the methods outlined by Rhodes et al.,[4] the total (overall) rate of loss of desired pregnancies (spontaneous losses plus pregnancy terminations) in our study was 5.8% in amniocentesis patients and 5.6% in CVS patients. Thus when this method is used to evaluate outcome our data further support the previous studies that there is no statistically significant difference in risk between CVS and amniocentesis.[4, 5] Use of this "corrected" data allows for a more valid comparison between techniques and increases both the statistical power (>80%) and our confidence in our findings that there is no difference in loss after CVS or amniocentesis.[12] Although there are inherent limitations when data from other patient populations are used, the essentially identical loss rates in this study strongly suggest that CVS does not have an increased risk of fetal loss if performed by experienced personnel.

The incidence of preterm delivery in the CVS and amniocentesis groups was not different and supports the results reported in both collaborative trials.[4, 5] We noted a slight, but significant, increase in birth weight of infants in the CVS group compared with those in the amniocentesis group. This outcome may reflect subtle differences in socioeconomic factors that were not included in the demographic data obtained on each patient. Our study suggests that long-term complications from CVS are not increased over those encountered when amniocentesis is used.

In summary, the present investigation supports previous suggestions that CVS is a safe procedure. There is no significant increase in fetal loss or long-term pregnancy complications over that seen with amniocentesis. Alternatively, our results indicate that despite extensive operator and laboratory experience, obtaining and successfully culturing a sample is significantly more likely with amniocentesis. Of patients in the CVS group, 24 required a subsequent diagnostic procedure (patients with mosaicism, procedure or culture failures), whereas only three patients in the amniocentesis group had further studies (patients with procedure failures or mosaicism). Patients seeking prenatal diagnosis should be informed of these differences, especially in beginning programs in which the prevalence may be much higher. However, the relative safety of CVS and earlier gestational age at which it can be performed may outweigh this disadvantage. Overall, we believe CVS offers a safe and reliable alternative to amniocentesis.

We are indebted to Siva Thiagarajah, MB, BS, Patricia Abbitt, MD, and Nancy Breeden, RN, for their excellent guidance in ultrasonography. In addition, we acknowledge Joan Adkin, MD, and the cytogenetic technicians for their careful chromosome studies. Bar-

bara J. Burkett, PhD, provided invaluable statistical assistance. The technical assistance of Iris Coiner, Jean DePiro, Rachel Baughman, Patti Roach, Bonnie Lawson, and Carolyn Morris was much appreciated.

Second-trimester placental biopsy for rapid fetal karyotyping

A. D. Cameron, MB, ChB,[a] A. M. Mathers, MB, ChB,[a] S. Wisdom, MB, ChB,[a] J. Johnstone, RGN,[a] J. R. M. MacKenzie, MB, ChB,[a] J. J. Walker, MB, ChB,[a] S. J. Imrie, BSc,[a] G. W. Lowther, BSc, DipRCPath,[b] and J. M. Connor, BSc, MD[b]
Glasgow, Scotland

Since January 1988 the technique of first-trimester chorionic villus sampling (placental biopsy) has been extended to include cases in the second trimester. To date, 40 procedures have been performed. The main indication for the late chorionic villus sampling was a low serum α-fetoprotein value in association with an increased risk for Down syndrome (n = 28), abnormal ultrasonographic finding (n = 7), and failed amniotic cell culture (n = 3). Successful karyotype results were achieved in all but two cases. Most results were obtained within 48 hours with direct cytogenetic techniques. No cases of mosaicism were found. The highest yield of abnormal karyotypes was obtained from the cases with abnormal ultrasonographic findings (one trisomy 21, two 45,X). One case of trisomy 21 was identified in the 28 cases of low serum α-fetoprotein. No spontaneous losses have occurred. The technique is easy to learn, does not differ from first-trimester procedures, and may have a lower complication rate than cordocentesis.The reporting of cases to the *CVS Newsletter* should help evaluate late chorionic villus sampling as another method for rapid fetal karyotyping. (AM J OBSTET GYNECOL 1990;163:931-4.)

Key words: Placental biopsy, rapid fetal karyotyping, chorionic villi

Amniocentesis performed in the second trimester of pregnancy is still the "gold standard" test for the detection of fetal karyotype abnormalities. The disadvantage of this technique is that results are not available for 2 or 3 weeks. This is particularly unacceptable in late pregnancy, when knowledge of the fetal karyotype is essential for obstetric management when certain structural defects are present in the fetus.

Chorionic villus sampling or placental biopsy, unlike amniocentesis, does not require culture for immediate karyotype analysis. The direct method as described by Simoni et al.[1] yields results within 48 hours. The technique has been shown to be feasible when performed

Table I. Midtrimester placental biopsy ($N = 40$)

Factor	*Average*	*Range*
Patient age (yr)	32.4 ± 5.0	19-42
Gestational age (wk)	18.6 ± 2.1	15-26
Weight of sample (mg)	11.1 ± 5.9	1-2

Table II. Karyotype abnormalities detected by midtrimester placental biopsy

Indication for biopsy	*Karyotype*
Oligohydramnios	47,XY + 21
Cystic hygroma	45,X
Low maternal serum α-fetoprotein	47,XY + 21
Fetal hydrops	47,XY + 21
Cystic hygroma	45,X

after the first trimester.[2-6] This study presents the clinical and laboratory results of an initial experience with placental biopsy in the second trimester of pregnancy.

Patients and methods

The technique of first-trimester chorionic villus sampling is already well established in our center. The procedure used for the second-trimester placental biopsies was identical to the method used for chorionic villus sampling in the first-trimester procedures.

The recruited patients provided informed consent before the procedure. The maternal abdomen and ultrasound transducer were cleaned with a topical application of chlorhexidine gluconate (0.5%). No local anesthetic was given. Ultrasonographic scanning was performed to determine the placental location. Patients with a deep posterior placenta were excluded from the study because placental biopsy would have required a transamniotic approach with possible increased fetal hazard. Sampling was done under real-time ultrasonographic guidance with a curvilinear probe (Diagnostic Sonar 128, 3.5 MHz, Diagnostic Sonar, Livingston, Scotland). A 16-gauge intravenous cannula with a stylet was introduced through the maternal abdominal wall until it just penetrated the uterine wall directly above the chosen sampling site. The stylet was removed and a 20-gauge 90 mm spinal needle with a stylet was then introduced. When the echo of the needle tip was clearly visible within the placenta, the stylet was removed and was replaced by a 10 ml syringe. The needle was then moved back and forth within the substance of the placenta close to the chorionic plate with 10 ml of constant suction. This action was continued for approximately 10 to 15 seconds and the needle was then withdrawn.

Aspirated tissue was washed in a 10 cm plastic Petri dish with Ham's F-10 solution and was examined by eye to estimate tissue weight. When a suitable quantity of tissue was seen, the sample was taken to the laboratory for processing. At the end of the procedure the fetus and the placenta were carefully examined and any abnormal findings were noted.

In the laboratory the villi were washed in fresh media, cleaned, and sorted to remove blood clots and carefully inspected under an inverted microscope to remove any maternal decidua. An estimate of villus weight was made according to reference standards; then 2 to 3 mg of tissue was removed for long-term cultures. The remaining villi were transferred to RPMI medium and incubated at 37° C for 1 hour before adding colcemid (0.1 μg/ml final concentration) for 2 hours. The villi were then harvested according to the method of Simoni et al.[1] for direct preparations. Cell cultures from villi were established in Chang medium and suspension harvests were prepared according to standard techniques. Direct preparations were analyzed on 10 cells stained with giemsa. In all cases G banding was attempted. Cultured preparations were analyzed from at least two cultures of G-banded cells.

Results

The technique of second-trimester placental biopsy was introduced in January 1988. In the first year of the study 12 procedures were done and an additional 28 biopies were performed in 1989. The overall results are shown in Table I. The high mean patient age reflects the number of patients who had the procedure performed because of an increased risk of aneuploidy because of low maternal serum α-fetoprotein estimation ($n = 28$). Two cases were performed because of previous karyotype abnormalities, and three procedures were performed because of failed amniotic fluid culture. Seven procedures were done when an abnormal ultrasonographic appearance suggestive of chromosomal abnormality was detected. Suitable samples of villi were obtained in 38 of the 40 cases. The mean weight of chorionic villi aspirated was 11.1 mg. This was achieved with either one or two attempts at aspiration. Four cases had only direct chromosome preparations performed. In five cases culture results only were achieved, and in 27 cases both direct and culture results were obtained. In two cases no result was obtained from placental biopsy. The average time for karyotype results to be obtained using culture techniques was 20 days (range, 16 to 30 days) and the mean time for direct results was 2 to 3 days (range, 1 to 6 days).

The highest yield of karyotype abnormalities was found in the cases with abnormal ultrasonographic findings (two cases of trisomy 21, two of 45,X). One other case of trisomy 21 was identified in the 25 cases of increased risk for Down syndrome (Table II). All

women whose fetuses had abnormal karyotypes elected to have termination of pregnancy. Except these pregnancy terminations, no cases of fetal loss have been reported. To date, 20 patients have been delivered with no neonatal complications reported. The other pregnancies are continuing.

Except for one case in which only tetraploid cells were seen on direct preparations and a 46,XX karyotype subsequently was obtained from cultures, there were no cases of discordant karyotypic findings or problems as a result of mosaicism on direct preparations or cultures in this series.

Comment

This study shows that the technique of chorionic villus sampling used in first-trimester cases can equally be applied in later pregnancies. The technique is easy to learn and has the advantage that preliminary karyotype results can be obtained within 2 to 3 days. This shortened interval helps to relieve patient anxiety and may influence obstetric decision making.

Patient selection methods for second-trimester placental biopsy are arbitrary, but in this study selection was limited to patients with an increased risk of having a fetus with an autosomal trisomy or to patients with a demonstrable fetal abnormality on ultrasonography and a significant chance of a karyotype abnormality. Screening for increased risk of autosomal trisomy is performed on all patients attending our center who wish maternal serum α-fetoprotein testing for the detection of neural tube defects. The risk of autosomal trisomy is calculated with figures previously reported.[7] An arbitrary cutoff level of 1:200 for Down syndrome was taken as the level at which patients are counseled concerning the risk of Down syndrome. Prenatal diagnosis by either amniocentesis or midtrimster placental biopsy is then offered to all patients with a risk $\geq 1:200$.

The decision to perform either amniocentesis or placental biopsy also depends on the placental site. In this study, unlike previous reports,[5] only anterior or posterofundal placentas were sampled by the technique described. No biopsies were attempted when amniotic sac puncture would have been required to obtain a sample. Placental location did not appear to influence the frequency of needle insertions. The results show that an adequate sample can be obtained in the majority of cases with a maximum of two needle insertions. Four cases had failed results; two of these were a result of inadequate sample size and the other two remain unexplained. Over the period of the study sample sizes have improved; the mean sample size for the last 28 cases was 15 mg. A sample size >10 mg was usually adequate for both direct and culture cytogenetic methods, but successful results were obtained in some samples as small as 5 mg. No relationship was apparent between the sample size and the time required to report both direct and culture results.

It appears that results of this study agree with the findings of previously reported studies on midtrimester placental biopsy in that the mitotic index does not fall with placental aging,[2-6] at least until 26 weeks' gestation, which was the latest gestation at which the procedure was performed. In the study by Nicolaides et al.,[2] successful karyotypes were obtained in two cases sampled in the third trimester (35 and 37 weeks). In a study by Wolstenholme et al.,[6] the mitotic index was variable and the quality of the preparations did not always correspond well with the quality and quantity of the specimen.

The main benefit of placental biopsy is that rapid karyotyping can be made available from direct cytogenetic techniques. It must be stressed that in this study the direct results were regarded as preliminary, and although the patient was told of these results, she was also told that a culture result would require another two weeks. However, it was thought that the direct results were sufficiently accurate to exclude a major karyotype abnormality such as trisomy 21. It should also be emphasized that in a relatively large number of cases (5/38, 13%) no direct results were achieved. This is in contrast to our laboratory's experience of first-trimester chorionic villus sampling in which inability to obtain direct results occurred in 4.6% of cases. A recent large study[8] reported a false-postive rate in direct preparations of first-trimester chorionic villus samples of 2.3%. This primarily comprised mosaicism confined to the trophoblast. Such a study stresses the need for confirmatory culture results. However, should culture results not be available because of a poor sample size, it is reassuring that no false-negative results were obtained in the direct cytogenetic preparations. In our laboratory's experience of first-trimester chorionic villus samples, 1% of direct preparations had a mosaic karyotype. However, on follow-up a false-positive rate of 0.75% was seen. No cases of mosaicism have been found in any of the second-trimester placental biopsies.

Of the abnormal karyotype results obtained, all were reported from direct preparations. Thus a result was available within 48 hours and this aided in the management of the case.

To date, except the patients who chose pregnancy termination, no cases of fetal loss have occurred after the procedure. These preliminary results are considered encouraging and are similar to the experience of 20 other centers worldwide that have now been incorporated into a late chorionic villus sampling registry.[9] The sampling technique is easy to learn, does not differ from first-trimester procedures, and may have a lower complication rate than cordocentesis.[10] The procedure is useful for patients who are seen too late for first-trimester prenatal diagnosis, for those who are esti-

mated to have a high risk of having a fetus with autosomal trisomy, and for those patients in whom an amniotic fluid cell culture fails. It may prove to be of particular value in cases of abnormal fetal anatomy as demonstrated ultrasonographically. Exclusion of a chromosome abnormality in such cases enables appropriate management of the anomaly in terms of in utero therapy or the mode of delivery. The reporting of cases to the *CVS Newsletter* in Philadelphia should help evaluate placental biopsy as another method for rapid fetal karyotyping.

We thank the members of the scientific staff in the Duncan Guthrie Institute of Medical Genetics, Glasgow.

The association of maternal floor infarction of the placenta with adverse perinatal outcome

Robert L. Andres, MD, William Kuyper, BA, Robert Resnik, MD, Kathleen M. Piacquadio, MD, and Kurt Benirschke, MD

San Diego, California

Maternal floor infarction of the placenta is a relatively rare disorder that on gross examination is characterized by a thickened gray-yellow maternal floor of the placenta with histologic evidence of massive fibrin deposition involving the decidua basalis and the contiguous villi. This lesion has been associated with fetal death, preterm delivery, and intrauterine growth retardation and is thought to be recurrent. Sixty cases of maternal floor infarction were identified in 48 women. Fetal death occurred in 24 of the 60 cases (40%). Preterm birth occurred in 21 of 36 (58.3%) live-born infants, and 19 of the 35 (54.2%) live-born infants for whom a birth weight was known had evidence of intrauterine growth retardation. Among the 41 multiparous patients in our series there were five documented recurrences (12.2%). Review of the past reproductive history of these 48 patients (196 pregnancies) demonstrated a significant incidence of fetal death (24.1%), intrauterine growth retardation (31.3%), and preterm death (35.4%). The association of fetal death and maternal floor infarction emphasizes the importance of a placental examination with all cases of fetal death and infants with intrauterine growth retardation. Given the risk of recurrence, the identification of maternal floor infarction should alert the clinician to the potential for growth retardation, preterm birth, and fetal death in subsequent pregnancies. (Am J Obstet Gynecol 1990;163:935-8.)

Key words: Placenta, intrauterine growth retardation, fetal death

Benirschke and Driscoll first described maternal floor infarction of the placenta.[1] The findings on gross examination include a thickened, yellow maternal floor with large deposits of fibrin. (Fig. 1). Microscopically, the villi are often encased in the fibrin and eventually become necrotic and avascular (Fig. 2). Maternal floor infarction is to be distinguised from the more common focal placental infarcts in that ischemic tissue necrosis is typically absent. The pathologic changes seen with preeclampsia (i.e., decidual vasculopathy) are absent in cases of maternal floor infarction and there is no evidence of acute or chronic villitis.

This entity has been reported to be associated with recurrent fetal death and intrauterine growth retardation[2-4] and yet it has not been explored in depth. The purpose of this investigation was to determine the incidence of maternal floor infarction of the placenta, to clarify its association with fetal death, IUGR, and preterm delivery, and to study the rate of recurrence in subsequent pregnancies.

Material and methods

The medical records of all patients with the diagnosis of maternal floor infarction of the placenta made at the University of California, San Diego, Medical Center from Jan. 1, 1976, through Dec. 31, 1987, were reviewed. The diagnosis of maternal floor infarction was confirmed by one of us (K. B.) and was based on a marked increase in fibrin deposition involving the decidual floor with villous encasement.

Fetal death was defined as a pregnancy loss at >20 weeks' gestation and preterm birth was defined as delivery at <37 weeks' gestation. The designation of IUGR was applied to newborns whose birth weights were less than the 10th percentile for gestational age.[5]

The incidence of fetal death, infants with IUGR, and preterm delivery was then determined for the 60 known cases of maternal floor infarction and for the 196 pregnancies constituting the total reproductive history of these 48 women. Medical records were available for all 60 of the known cases. Twenty-five of the 48 women were interviewed and provided additional information regarding their reproductive histories.

Results

Sixty cases of maternal floor infarction of the placenta were diagnosed in 48 women. Thirty were from inborn babies and the remaining 30 were from placentas sent to our institution for pathologic consul-

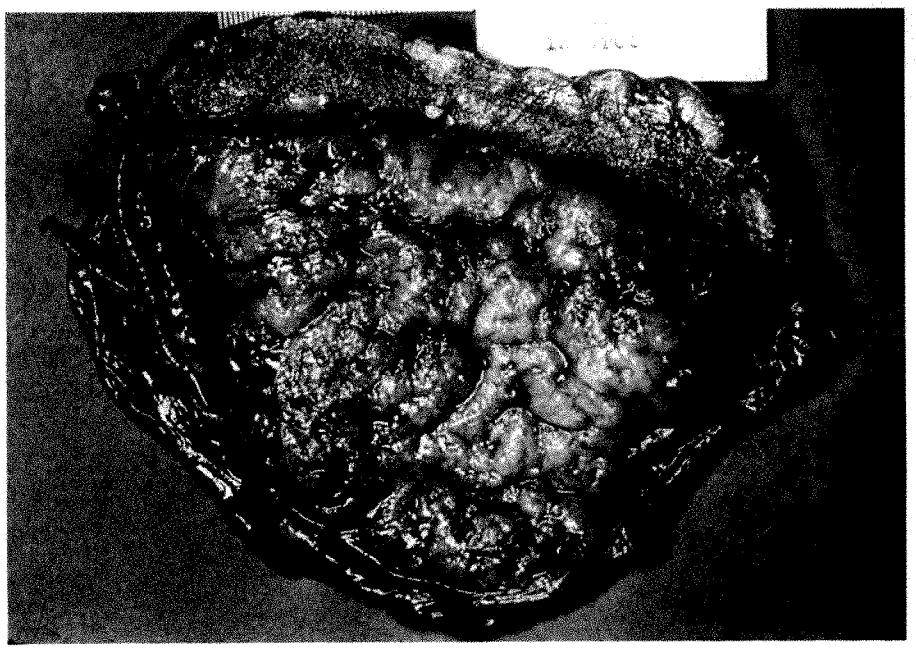

Fig. 1. Characteristic gross appearance of maternal floor infarction with thickened and yellow maternal floor.

Table I. Incidence of fetal death, IUGR, and preterm delivery in patients with maternal floor infarction of the placenta

Outcome	*Incidence*
Fetal death	24/60 (40%)
IUGR	19/35 (54%)
Preterm delivery	21/36 (58%)

tation. The incidence of maternal floor infarction was 30 in 32,182 (0.09%). The reproductive experience of these 48 women (including the 60 known cases of maternal floor infarction) totaled 196 pregnancies with 51 (26%) ending in either a spontaneous or an elective abortion. Thus 145 pregnancies were included in the analysis of the patients' collective reproductive histories.

Twenty-four of the 60 known cases of maternal floor infarction were associated with fetal death (40%) (Table 1). Ten of 24 (42%) occurred between 30 and 34 weeks of gestation. Overall 35 fetal deaths (24.1%) were reported in the 145 pregnancies that extended beyond the 20th week of gestation.

A birth weight less than the 10th percentile was recorded for 19 (54.2%) of 35 live-born infants delivered of patients with known maternal floor infarcts (Table I). Twenty of the 22 (91%) stillborn infants with known birth weights were below the 10th percentile. They were excluded from the analysis, given the difficulty in accurately assigning gestational age to an intrauterine fetal death.

Twenty-one of the 36 (58.3%) live-born infants with a known maternal floor infarction of the placenta were delivered at <37 weeks of gestation (Table I). Eleven patients were diagnosed with preterm labor that was unresponsive to tocolytic therapy, and there were indications for preterm delivery in the remainder. In the 110 live-born infants among the 48 women in our series, 39 (35.4%) were delivered before 37 weeks.

There were 41 multiparous patients, and 5 (12.2%) of these had documented recurrences. Table II outlines the details of these cases and demonstrates that multiple recurrences were documented in each of the five. Among patients with a maternal floor infarction, a placental examination was performed in 33 subsequent pregnancies. Thirteen (39%) showed gross and histologic evidence of recurrent maternal floor infarction of the placenta.

Comment

Our data suggest a lower incidence of maternal floor infarction than the 0.5% quoted by Naeye[3] in his series from the Collaborative Perinatal Study. The incidence of 0.09% in the current series represents >30,000 consecutive placental examinations from this institution alone.

The association of fetal death and maternal floor infarction in 40% of our 60 cases is striking. The fact

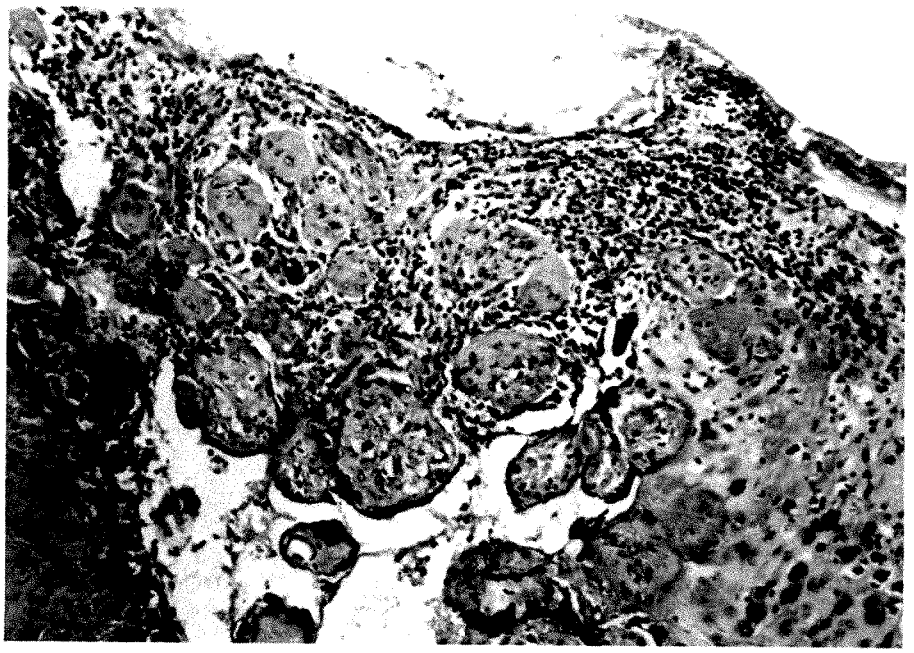

Fig. 2. Massive deposition of fibrin encasing villi with pronounced round cell infiltration.

that our series includes cases referred to one of us (K. B.) for pathologic consultation may introduce an ascertainment bias; however, the 30 cases seen in patients delivered at our institution were also associated with a fetal loss rate of 40%. Naeye[3] found a 17% rate of stillbirth in his series of patients with maternal floor infarction.

The finding of intrauterine growth retardation in 51% of our known cases of maternal floor infarction is similar to the findings of Naeye. Frequently the degree of growth delay is profound and is evident on ultrasonographic evaluation as early as the middle of the second trimester. Nickel[4] described a case of a 690 gm infant delivered at 36 weeks, without other risk factors for IUGR, whose placenta demonstrated the characteristic findings of maternal floor infarction.

The pathophysiologic basis of the fetal death and growth retardation is unclear. It has been suggested that the fibrin deposition interferes with perfusion of the intervillous space and that growth delay and fetal death result from chronic "placental insufficiency."

It has been suggested that maternal floor infarction is a recurrent lesion. Case reports have described recurrent fetal death and growth retardation in women with maternal floor infarction.[1-3] In addition, Naeye[3] found that multiparous women with evidence of a maternal floor infarction had twice as many unsuccessful previous pregnancies (stillbirths and miscarriages) as did multiparous women without maternal floor infarction. In our series we identified five women who had at least one documented recurrence of maternal floor infarction. The actual risk of recurrence is difficult to ascertain because routine placental examination is not performed in cases of growth retardation, fetal death, or preterm delivery. However, among those pregnancies that followed a maternal floor infarction and included placental examination, 39% showed gross and microscopic evidence of recurrent maternal floor infarction.

Table II. Perinatal outcome among patients with recurrent maternal floor infarction of the placenta

Patient No.	*Total pregnancies*	*Maternal floor infarctions*	*Fetal deaths*	*Preterm deliveries*
1	7	4	4	1
2	6	3	2	0
3	7	4	4	2
4	4	4	1	0
5	3	3	3	0

The association of maternal floor infarction with fetal death and intrauterine growth retardation should reinforce the value of a placental examination in such cases. The likelihood that this is a recurrent disorder suggests that once a maternal floor infarction is discovered, subsequent pregnancies are at risk for IUGR, fetal death, and preterm delivery. It would seem prudent to monitor these pregnancies for evidence of fetal growth delay and to perform careful antepartum surveillance to

detect fetal compromise. Delivery should be considered when fetal pulmonary maturity has been established.

This relatively rare but serious placental disorder should be included in the differential diagnosis of fetal death and idiopathic IUGR. Appropriate antepartum management of pregnancy in these patients is likely to improve their chances for a subsequent favorable outcome.

Placental transfer of cefazolin and piperacillin in pregnancies remote from term complicated by Rh isoimmunization

Charles E. L. Brown, MD, James T. Christmas, MD, and Roger E. Bawdon, PhD
Dallas, Texas

Although the administration of prophylactic antibodies for intrauterine transfusion is controversial, little information is available regarding placental transfer of antibiotics administered to the mother, or whether the presence of hydrops affects this placental transfer. Sixteen intravascular intrauterine transfusions were performed in 10 patients. Seven (10 procedures) patients were given 2 gm of cefazolin before the procedure and samples were obtained by fetal vascular access. Three patients (six procedures) were given 4 gm of piperacillin and samples were similarly obtained. Specimens were obtained for fetal serum, maternal serum, and amniotic fluid antibiotic concentration. The mean serum cefazolin concentration in hydropic fetuses was 18.04 ± 3.37 μg/ml, and in nonhydropic fetuses the concentration was 21.02 ± 17.8 μg/ml ($p = 0.72$). The mean fetal serum concentration of piperacillin was 22 ± 12 μg/ml. The placental transfer of both drugs was similar. We conclude that the transplacental passage of these antibiotics is prompt and that the presence of hydrops does not significantly impair the passage of cefazolin. (AM J OBSTET GYNECOL 1990;163:938-43.)

Key words: Placental transfer of antibiotics, hydrops, Rh isoimmunization

Intravascular intrauterine transfusion is a technique that is gaining wide acceptance for management of fetuses with severe blood group isoimmunization. Many modifications of the basic technique have been described, and some authors suggest use of antibiotic prophylaxis to prevent intraamniotic or fetal infection.[1] There are few data available to evaluate the potential fetal benefit of antibiotic prophyalxis, which may be of particular importance in cases of hydrops in which there may be impaired passage of an antibiotic agent across an edematous placenta. The purpose of this study was to determine to what extent maternally administered antibiotics were transferred to the fetus and whether fetal hydrops had an impact on this phenomenon. Cefazolin is a relatively inexpensive first-generation cephalosporin and is frequently used for prophyalxis for both obstetric and gynecologic procedures. Piperacillin is an extended-spectrum penicil-

lin agent with activity against a variety of anaerobic and aerobic organisms isolated in infections in women.[2]

Material and methods

Ten patients who had a total of 16 transfusions were managed with intrauterine exchange transfusion by direct intravascular injection. Nine patients had antibodies to Rh_o(D) antigen and were thought to be severely affected on the basis of ultrasonographic findings of hydrops, optical density measurements of amniotic fluid at 450 nm, or both, or severe anemia noted on prior percutaneous fetal blood sampling. The procedure for transfusion was modified according to the technique of Grannum et al.[3] In addition to sedative medications, the patients were administered either 2 gm of cefazolin or 4 gm of piperacillin intravenously immediately before the procedure. The needle was initially inserted into the amniotic cavity and a specimen of amniotic fluid was obtained. The needle then was advanced into the umbilical vein and an initial 3 to 5 ml fetal blood specimen for determination of hematocrit and serum cefazolin levels was obtained. A maternal blood specimen for determination of the maternal serum cefazolin level was obtained at the time of fetal vascular access. Except that specimens were obtained for antibiotic analysis, the exchange transfusions were accomplished as previously described.[3] Hydrops was defined as the presence of an obvious effusion in two or more body spaces. In all cases of hydrops the fetal hematocrit level was <16%.

Amniotic fluid and serum concentrations of cefazolin were determined with paired samples and high-pressure liquid chromatography as described previously.[4] There were no modifications in the acetonitrile dichloromethane phase-extraction procedure, which consisted of 12% acetonitrile and 88% 0.10 mol/L sodium phosphate buffer, pH 6.1. The flow rate was 2.0 ml/min and the detector was operated at 229 nm. The components of the high-pressure liquid chromatography system consisted of a 30 cm C_{18} μBond-a-pak column (Waters Associates, Milford, Mass.), model 6000-A pump, a model 710B Waters Intelligent Sample Processor, and a model 481 detector. Specimens were run in duplicate. Peaks were recorded on a 10 mV chart recorder at chart speed of 0.5 cm/min.

Statistical analysis was performed with Student's *t* test for paired samples. Regression analysis was used to compare the interval from antibiotic administration to sampling and maternal and fetal antibiotic levels.

Results

The results for the patients who received cefazolin are summarized in Table I. There was no correlation between maternal and fetal serum cefazolin levels ($r = 0.012$; $p = 0.973$). The presence of hydrops did not significantly affect the fetal serum cefazolin level. The mean fetal serum cefazolin concentrations in the hydropic and nonhydropic fetuses were 18.0 ± 3.3 and 21.0 ± 17.8 μg/ml, respectively ($t = 0.37$; $p = 0.72$). There was no difference in sampling times of these groups.

As might be expected, the time from antibiotic administration to sampling was correlated with maternal serum of cefazolin level ($r = 0.731$; $p = 0.016$; Fig. 1). As shown in Fig. 2, this relationship could not be demonstrated for fetal serum cefazolin levels ($r = 0.455$; $p = 0.19$); however, the sample size was small. There was a trend for levels to increase with time, suggesting a cumulative transfer effect.

The results for the patients who received piperacillin are summarized in Table II. There were no hydropic fetuses in this group. There was no correlation between maternal serum and fetal serum piperacillin levels ($r = 0.33$; $p = 0.591$). The trend for decreasing ma-

ternal and increasing fetal antibiotic level also was seen for piperacillin. There was no statistically significant correlation for either maternal or fetal serum levels with time ($r = -0.567$; $p = 0.24$ and $r = 0.191$; $p = 0.76$, respectively), although the sample size is small.

The amniotic fluid concentration was very low for both cefazolin and piperacillin.

Comment

Although no clear-cut evidence exists to justify the use of antibiotic prophylaxis for intrauterine transfusions, this has been the practice at Parkland Memorial Hospital for both intraperitoneal transfusions and more recently intravascular transfusions, and is a practice empirically adhered to by others.[1, 5] The organism most often implicated in posttransfusion infection is *Staphylococcus aureus,* which is probably introduced by needle contamination at skin puncture,[5-7] although recently other bacteria have been reported to cause amnionitis afer percutaneous umbilical blood sampling.[8] It has recently been demonstrated at our institution that the level of cefazolin necessary for a mean inhibitory concentration of 90% of isolates was 8 μg/ml for coagulase-negative *Staphylococcus* and 2 μg/ml for *S. aureus* organisms.[9] The mean fetal serum cefazolin concentration clearly met this level; only one determination was less than the 8 μg/ml level for the 90% mean inhibitory concentration of the coagulase-negative *Staphylococcus.*[10] It is of interest that this low level was in a nonhydropic fetus (patient no. 2). This underscores the lack of relationship between the presence of hydrops and transplacental passage of cefazolin.

The fact that there was no difference in placental transfer of cefazolin regardless of the presence of fetal hydrops is of particular interest. Some authors have suggested that hydrops may alter placental transfer of antiarrhythmic drugs.[11] Our data suggest that comparable levels of cefazolin are achieved in all fetuses regardless of the presence or absence of hydrops, although this interpretation is limited because of the small number of patients available for study. Similarly, the level of piperacillin necessary for a 90% mean inhibitory concentration was 16 μg/ml for coagulase-

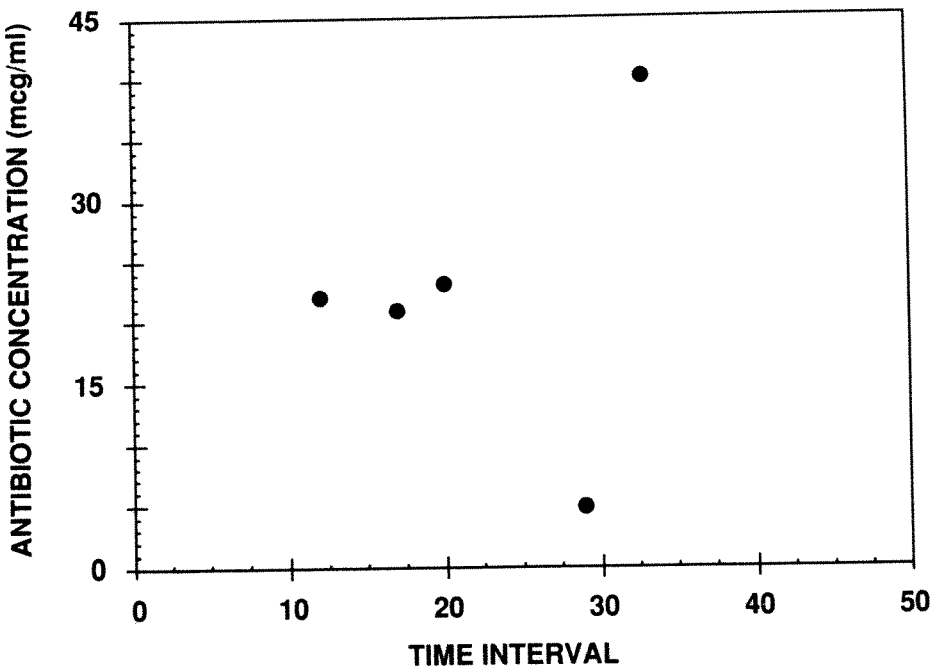

Fig. 4. Fetal serum piperacillin levels versus time in minutes from maternal drug administration until sample obtained.

negative *Staphylococcus* and 16 μg/ml for *S. aureus* in the study mentioned above.[9] This level was rapidly achieved in all but one nonhydropic fetus.

The apparent rapidity of placental transfer is an important issue. It has recently been shown that early antimicrobial treatment of acute chorioamnionitis results in a marked decrease in the incidence of maternal complications and neonatal sepsis.[12] In that series of maternal bacteremia infections and culture-proved neonatal sepsis, all cases were caused by staphylococci or nonenterococcal streptococci, against which cefazolin or extended-spectrum penicillins provide good activity. If placental transport to the fetus is a factor in treatment, we have demonstrated that this occurs rapidly after dosing.

Although our number of observations is limited, the fetal/maternal ratio is approximately 0.16 for both drugs, with adequate levels for *Staphylococcus* being achieved in most cases. Similar results with cefoxitin and mezlocillin have been recently reported.[13] The amniotic fluid concentration was low, although this may increase with time as the fetus has renal clearance of the drugs. This study did not address whether cefazolin or piperacillin prevents transfusion-related chorioamnionitis; however, it did afford the opportunity to evaluate the transplacental delivery of these agents. Because of the rapid placental transfer of these agents, we believe that they may be reasonable agents for the treatment of acute chorioamnionitis even when delivery appears imminent. Further investigation of placental transfer of other antimicrobial agents to determine those with the greatest potential for fetal-neonatal and maternal benefit is warranted.

Ultrastructural aspects of preeclampsia

II. Mitochondrial changes

Douglas R. Shanklin, MD, and Baha M. Sibai, MD
Memphis, Tennessee

Biopsy specimens were obtained under direct vision at the time of cesarean section from 47 patients (35 with preeclampsia and 12 normotensive patients) and from four women with cesarean section hysterectomies (all normotensive) as an extension of previous work. Tissues were obtained from the myometrium near the placental bed and from the opposite side of the uterus. Skin biopsies were also obtained from eight women with preeclampsia and liver biopsies were obtained from two patients with acute microvesicular fatty change of pregnancy (one with and one without concomitant preeclampsia). Specimens were examined histologically and by electron microscopy. Mitochondrial changes in small vessels, principally venules, in myometrial smooth muscle, myometrial interstitial cells, circulating leukocytes, epidermal and dermal cells, and hepatocytes were examined and compared between women with preeclamptic and normotensive pregnancies. These findings were then compared with mitochondria from 500 biopsies over the same 3-year interval to assess the possible role of delay in tissue fixation. There were 12 other biopsies from nonpregnant women of childbearing age. As further control on artifact, other specimens were initially sampled immediately in the operating room and then serially for up to 2 hours later. Artifact as a basis for the mitochondrial changes was ruled out by these procedures. Normal mitochondria undergo a morphologic conformational sequence with physiologic changes in substrate, oxygen consumption, adenosine diphosphate, and respiratory rate. The mitochondria of preeclamptic tissues show a central disruption that is outside this normal sequence or cycle. This disruption occurs more often and is more severe in preeclampsia than in normotensive pregnancies. In addition, the hypertrophic smooth muscle of the pregnant uterus has a complex of cytoplasmic organelles in a paranuclear location, usually apical, that contains a variable mixture of glycogen, the Golgi apparatus, endoplasmic reticulum, mitochondria, and small unidentified microvesicles. This complex has the location and appearance suggestive of a myometrial "power pack" of significance in metabolism and contraction. The presence of similar mitochondrial changes in a limited sample of nonuterine tissues is suggestive of a systemic metabolic disorder as an important feature of preeclampsia. (AM J OBSTET GYNECOL 1990;163:943-53.)

Key words: Mitochondrial injury, preeclampsia, systemic metabolic effects, cytoplasmic complex of smooth muscle organelles, pregnancy uterine smooth muscle changes

Recent observations,[1-12] including some from our laboratories,[11] have suggested a close relationship between mitochondrial energy states, preeclamptic toxemia (gestosis humanis), familial patterns for preeclampsia, and nutritional and metabolic aspects of pregnancy. The evidence lies in the observation of a pattern of mitochondrial injury[11] that extends beyond the basic cycle of mitochondrial conformational change.[2-4, 6, 8, 9]

It is well established that mitochondria undergo a morphologic conformational sequence with physiologic changes in substrate, oxygen consumption, adenosine diphosphate, and respiratory rate.[2-4, 6, 8, 9] The principal

forms are *orthodox* (an open pattern with cristae) and *condensed* (a noncristal matrix with inner spaces). State 1 is characterized by an increased density of the cristae correlated with a low substrate and adenosine diphosphate energy state and with a slow respiratory rate (the condensed conformation) through an open or orthodox pattern during which phosphorylation of adenosine diphosphate occurs.[2] Subsequent states 2 through 5 have systematic but independent variations in substrate, adenosine diphosphate level, respiratory rate, and oxygen content that are not always coordinated with oxidative phosphorylation; these states have variable time courses and mixes of the condensed and orthodox conformations.[2] The details are beyond the scope of this article and will be discussed in a future article.

The injury pattern reported in this study has features more closely identified with particular aspects of the

(Original transmission electron microscopic magnification, × 16,000.)

mitochondrial energy cycle, specifically postcalcium release phosphate-dependent matrix change, which leaves a membrane whorl[4] as a marker of the preceding events.

The endothelium of small uterine vessels in preeclampsia often has a diffusely swollen cytoplasm, and the mitochondria commonly rupture into the cytosol or vascular lumen.[11]

The purpose of this article is to describe and compare mitochondrial changes in normotensive and preeclamptic pregnancies as an extension of our previous work.[11]

Material and methods

Informed consent for placental bed and uterine boundary, liver, and skin biopsies was obtained from various patients in the prenatal clinics of the E. H. Crump Hospital who were scheduled for cesarean sec-

tion on obstetric or perinatal grounds. A total of 47 patients, 35 with preeclampsia (systolic blood pressure >140 torr, diastolic blood pressure >90 torr, or both, with proteinuria >300 mg/24 hr), and 12 normotensive women had biopsies. Four cesarean section hysterectomy biopsy samples from normotensive patients were studied, for a total of 51 patients (16 normotensive and 35 hypertensive). At the time of cesarean section biopsy specimens approximately 0.8 × 0.6 × 1.0 cm were excised by sharp dissection and were immediately placed in the appropriate fixative. Placental site samples were taken to include underlying myometrium just after placental removal, and comparable nonsite samples were taken from the opposite uterine wall. Liver and skin biopsies were taken in accordance with ordinary surgical procedures. On receipt in the pathology laboratory appropriate accession numbers were assigned and the samples were trimmed into pieces for paraffin or plastic embedding according to standard techniques, beginning with 10% neutral-buffered aqueous formalin for histology and net 1.0% glutaraldehyde-buffered in Sorenson's solution for ultrastructural study.

Paraffin sections were cut at 5 μm and were stained by hematoxylin and eosin for light microscopy. Histologic preparations were available for all 51 patients.

Plastic sections for electron microscopy were prepared in the usual manner with lead acetate staining of thin-cut sections at 0.4 μm. Electron micrographs were taken at × 1600 to × 25,000 original magnification with a Zeiss EM-10C electron microscope and were printed at an average additional enlargement of 2.7 times. Transmission electron micrographs were available for 29 of 35 women with preeclampsia and for 13 of the 16 normotensive patients.

During these studies two patients with acute microvesicular fatty liver of pregnancy (one with and one without concomitant preeclampsia) had liver biopsies as part of their diagnostic workup. Both biopsies were studied by electron microscopy. Preliminary observations indicated the need to examine tissues other than uterus. Accordingly, skin biopsies were also obtained from eight women with preeclampsia at the time of cesarean section delivery. These findings were compared with mitochondria in 500 electron microscopy biopsies over the same 3-year interval to assess the possible role of delay or artifact in tissue fixation. Twelve of these samples were from nonpregnant women of childbearing age. As further control of artifact, several other specimens were initially sampled immediately in the operating room and then serially for up to 2 hours later. Artifact as a basis for the mitochondrial changes was ruled out by these procedures.

Results

Mild, focal mitochondrial changes were observed in some normotensive specimens. Because there was a marked progression of both number and severity of injured mitochondria in women with preeclampsia, the initial change can be considered an effect of underlying metabolic adaptation or stress from pregnancy itself.

The earliest change was a clearing within the matrix of the mitochondria that appeared as a zonal loss of cristae, usually eccentric. This change in mitochondria resembled condensed deenergized state 5[2, 3, 6, 8] but lacked the discrete folds of the matrix and the previously described "buttonhole" openings[2, 3, 6, 8] in the dense zones. This clearing became larger and sometimes the mitochondrion bulged distinctively. Cristal material was then compressed against the lateral membrane and some ghost cristae become apparent. Another severe form occasionally seen in the preeclamptic group was a diffusely enlarged mitochondrion, up to twice the normal size, that basically resembled energized state 4,[2, 3, 6, 8] but with cristae bent against the lateral membrane. In these more advanced forms a laminated roll or whorl was seen. This pattern has been identified as a remnant feature of postphosphate calcium release in state 6.[4] These changes were present in small uterine and cutaneous vessels, in both smooth muscle and the interstitium of the myometrium, in circulating leukocytes, and in parenchymal skin cells, indicating a systemic change. The liver mitochondria in one patient with both preeclampsia and microvesicular fatty change showed mild injuries of a similar type, but these were changes not seen in the liver biopsy of one patient without preeclampsia. Another general observation from these samples is that mitochondria in the several sites have a different overall appearance. Liver mitochondria have a more typical orthodox configuration, whereas those elsewhere tend to have a condensed appearance.

Vascular endothelial changes. The specific changes included markedly swollen mitochondria that bulge, sometimes into the vascular lumen with resultant rupture and release of their contents, a prelude to endothelial erosion.[11] Another special feature is that diffuse cytoplasmic swelling is seen; this occurs infrequently in normal pregnancy and much more often and more severely in preeclampsia.[11] This is an alternate pathway to erosion. Some random electron micrographs have shown both mitochondrial and diffuse cytoplasmic swelling in endothelial cells of preeclamptic biopsy specimens. Injured mitochondria were either quite isolated or clustered. The clusters usually showed a range of mitochondrial size and degree of injury (Fig. 1). Several electron micrographs of placental site and elsewhere showed similar mitochondrial changes in circulating leukocytes (Fig. 1).

Myometrium. Mitochondria are found in both myometrial smooth muscle and in various interstitial cells. Some of the latter are oncocytic; that is, they have large numbers of mitochondria. In normotensive pregnancy

Fig. 3. Apical location of myometrial paranuclear complex (nucleus, *N*). Complexes vary in relative amounts of glycogen *(G)*, mitochondria, Golgi, and endoplasmic reticulum *(E)*. In this example the complex is small in this plane, with closely packed endoplasmic reticulum below and some glycogen to the right. Seven mitochondria are present (three are labeled, *m*) and all have a centrally cleared zone. (Original electron microscopic magnification, ×6000.)

these have an orthodox configuration (Fig. 2). The mitochondria of myometrium vary in number and size, but in muscle cells that show gestational hypertrophy they are in paranuclear locations, often apical, where they are mingled with the Golgi apparatus and deposits of glycogen (Figs. 3 to 5). Most smooth muscle mitochondria are found in the paranuclear complex. These mitochondria show the same type, range, and degree of changes described above. Extreme magnification shows some mitochondria to be only zonally injured, whereas others are recognizable as mitochondria only from a few remnant cristae and the double outer envelope (Fig. 5).

Skin

Similar mitochondrial changes were found in dermal connective tissue cells, in epidermal germinal layer cells (Fig. 6), in leukocytes of preeclamptic specimens, and in skin vessels.

Liver

Liver biopsies for diagnosis of microvesicular fatty change (Figs. 7 and 8), a metabolic disorder with some features of Reye's syndrome, also show mitochondrial injury in preeclampsia (Fig. 8) but present an orthodox appearance when the microvesicular lesions occur alone (Fig. 7). The extent to which either lesion might

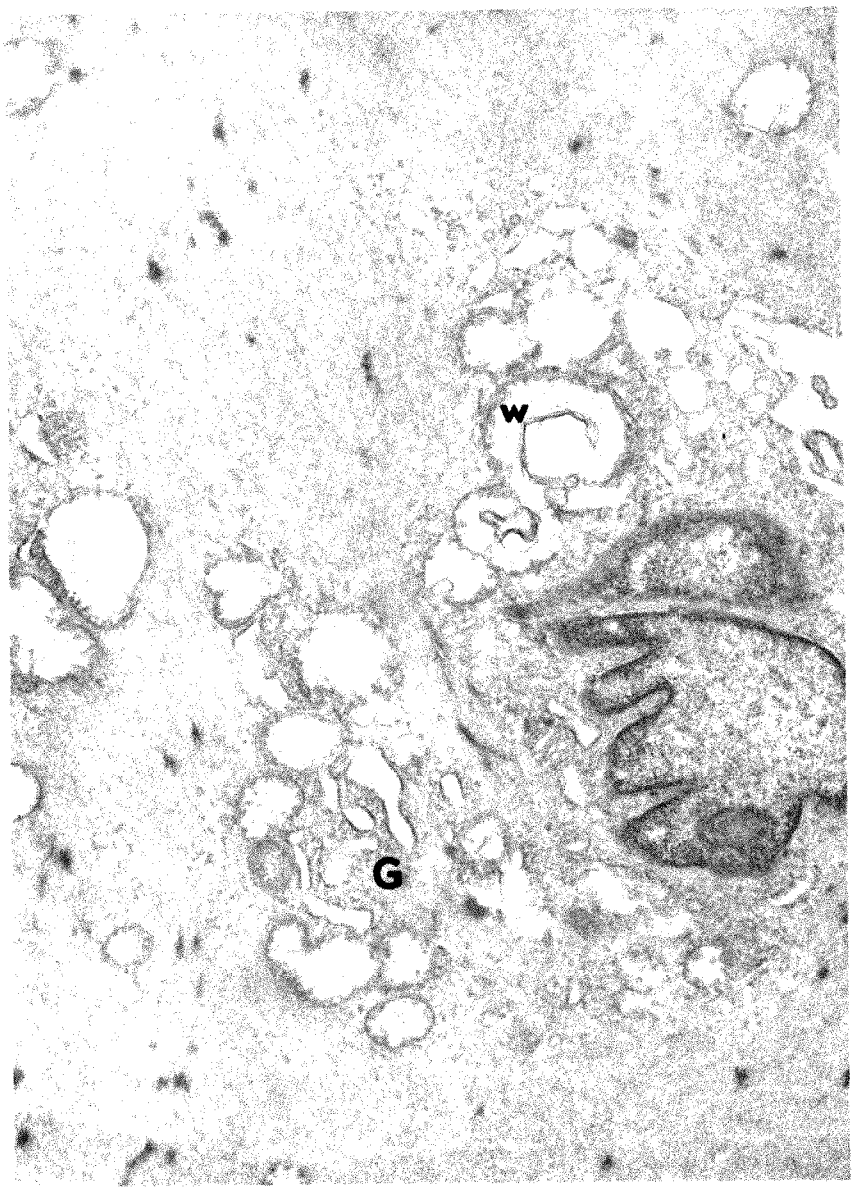

Fig. 4. Apical location of larger myometrial paranuclear complex. Advanced injury to mitochondria in severe preeclampsia with "whorls" *(W)* within cleared mitochondria *(center)* and moderately dilated tubular Golgi *(G)* irregularly displayed about the complex. There is light stippling of glycogen close to the tip of the nucleus and within the complex below and to the left. (Original transmission electron microscopic magnification, ×8000.)

influence the appearance or functional severity of the other is unclear from this limited ultrastructural survey. However, it does serve to show another systemic aspect of the mitochondrial changes in preeclampsia.

Comment

Because cell vitality is dependent on intact mitochondria capable of the cyclic sequence of reconformation, with all the metabolic and energy transfer implications that reconformation portends,[2-4, 6, 8, 9, 12] pathologic deviations of the type described in this study are evidence of a potentially profound metabolic disturbance. The metabolic implications of preeclampsia might be best assessed from within closely controlled studies on pregnancy nutrition,[10] with special reference to two different but likely integrated lines of consideration: the competency of the protein matrix of the mitochondrion[5, 12] and the energy reserves and nutrient

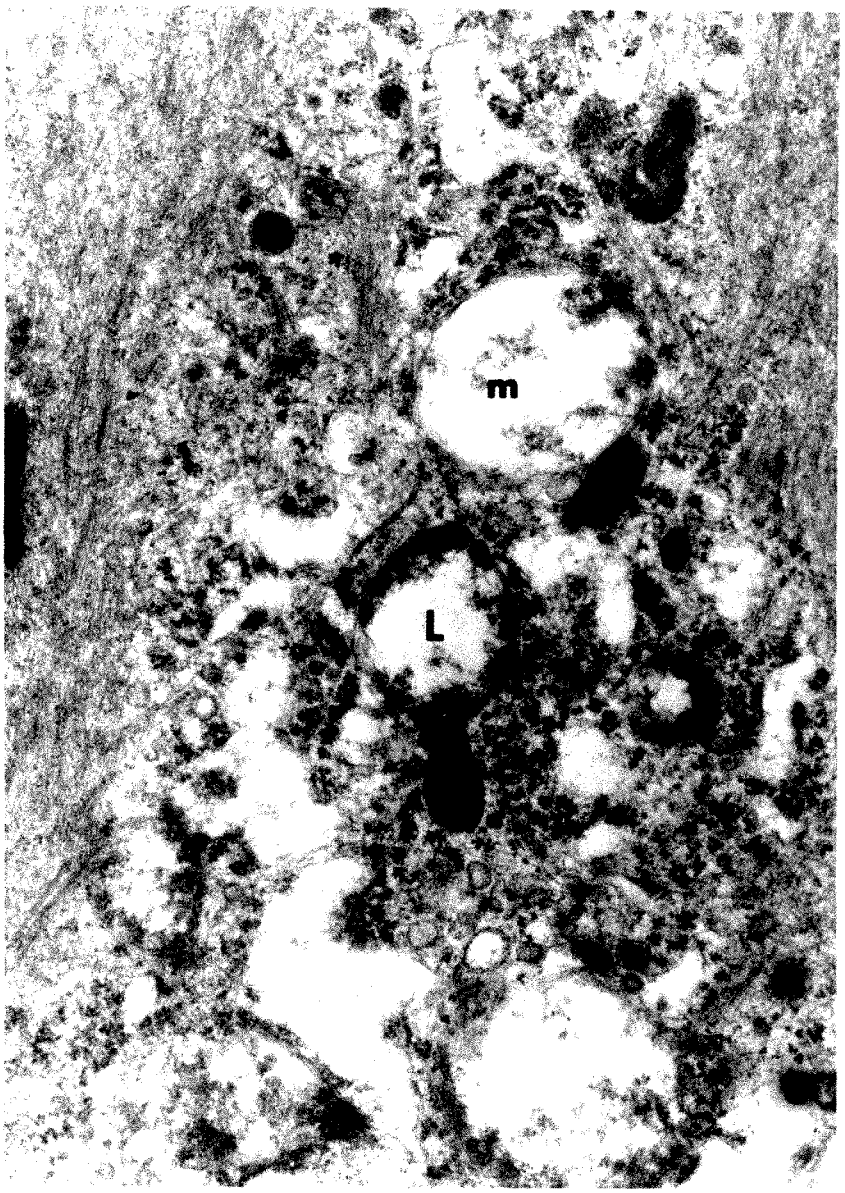

Fig. 5. Biopsy specimen of patient with severe preeclampsia shows mitochondrial injury in a myometrial apical paranuclear complex. Note moderate deposit of granular glycogen. The dumbbell-shaped mitochondrion *(L)* just below the center is only partially cleared. Immediately above it is another, somewhat larger mitochondrion with few cristal remnants *(m)*. (Original transmission electron microscopic magnification ×16,000.)

requirements for healthy evolution of the pregnancy, including fetal growth and maturation.[10] The former point is clearly related to the amino acid pool drawn from the initial maternal reserves and subsequent food intake, especially during the period of most rapid uterine and fetal growth.[10] Maintenance of mitochondrial integrity, like that of other aspects of cell machinery, is dependent on the proteins and enzymes necessary and available at the time of organelle renewal. The second point derives from the relationship between the energy costs of pregnancy and the conversion efficiency of maternal cells and tissues that lie between ingested food and the fetal side of the placental barrier.[10] It is not possible from present observations of these mitochondria to focus more specifically on the metabolic or nutritive aspect most involved in their injury.

The finding of a paranuclear complex in uterine smooth muscle that contains the principal parts of a

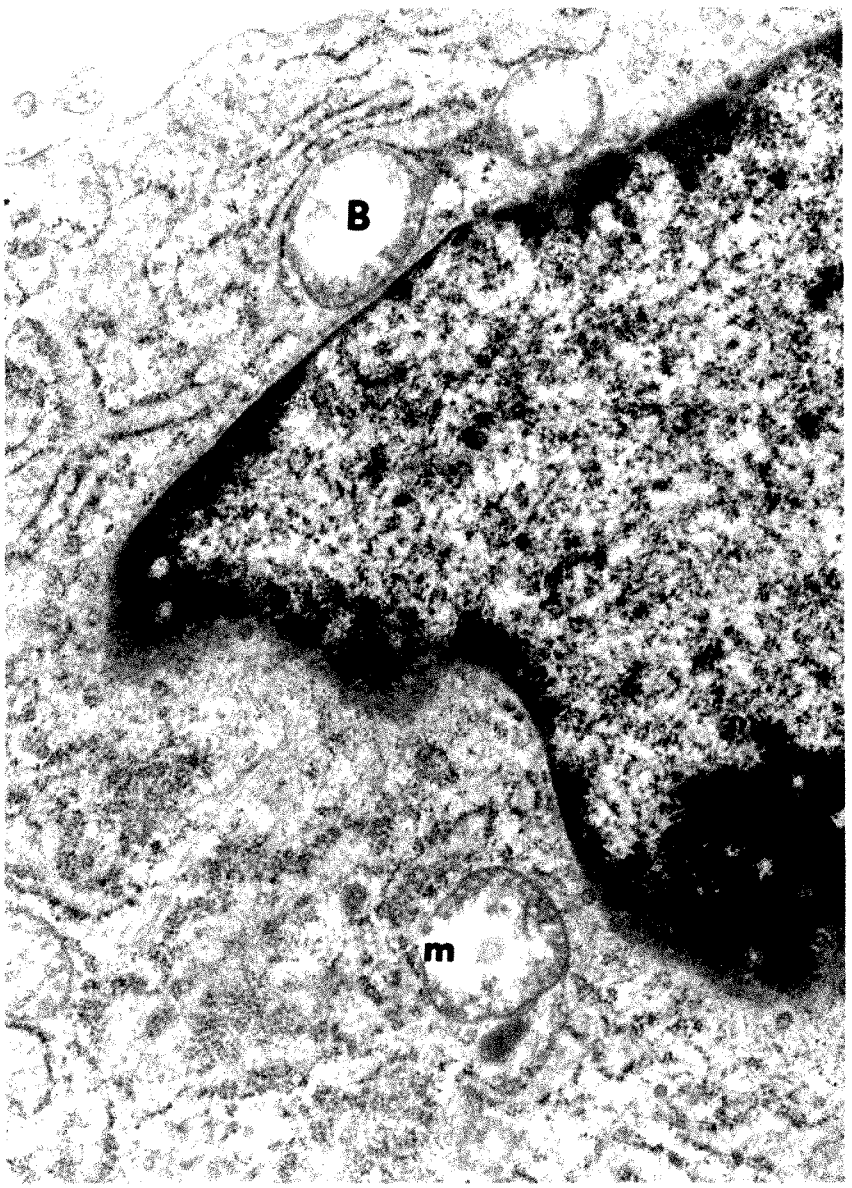

Fig. 6. Sample from patient with severe preeclampsia depicts mitochondrial injury in germinal layer of epidermis. Lower mitochondrion *(m)* has a small contained "whorl," and the dumbbell-shaped upper mitochondrion *(B)* has cavitary change in both lobes. (Original transmission electron microscopic magnification, ×12,000.)

bioenergetic engine, mitochondria, Golgi, glycogen, and endoplasmic reticulum (Figs. 3 to 5) serves as a possible line of further investigation into the pathogenesis of gestosis. It has already been noted that aerobically active organs with a high demand for adenosine triphosphate, such as brain, retina, and cardiac and skeletal muscle, are especially vulnerable to the effects of mitochondrial disorder.[5-7] We suggest that the pregnant uterus is a similar high metabolic zone and that it may qualify for pathophysiologic problems in a similar fashion. The examples we have illustrated (Figs. 3 to 5) are only a small part of the overall range of the paranuclear complex. In some cases they extend along the nucleus and become biapical, in others the complex is much larger. Generally, but not exclusively, the larger complexes have more glycogen. This factor might relate the fundamental development of the complexes to the ultimate functional adequacy of the uterine unit.

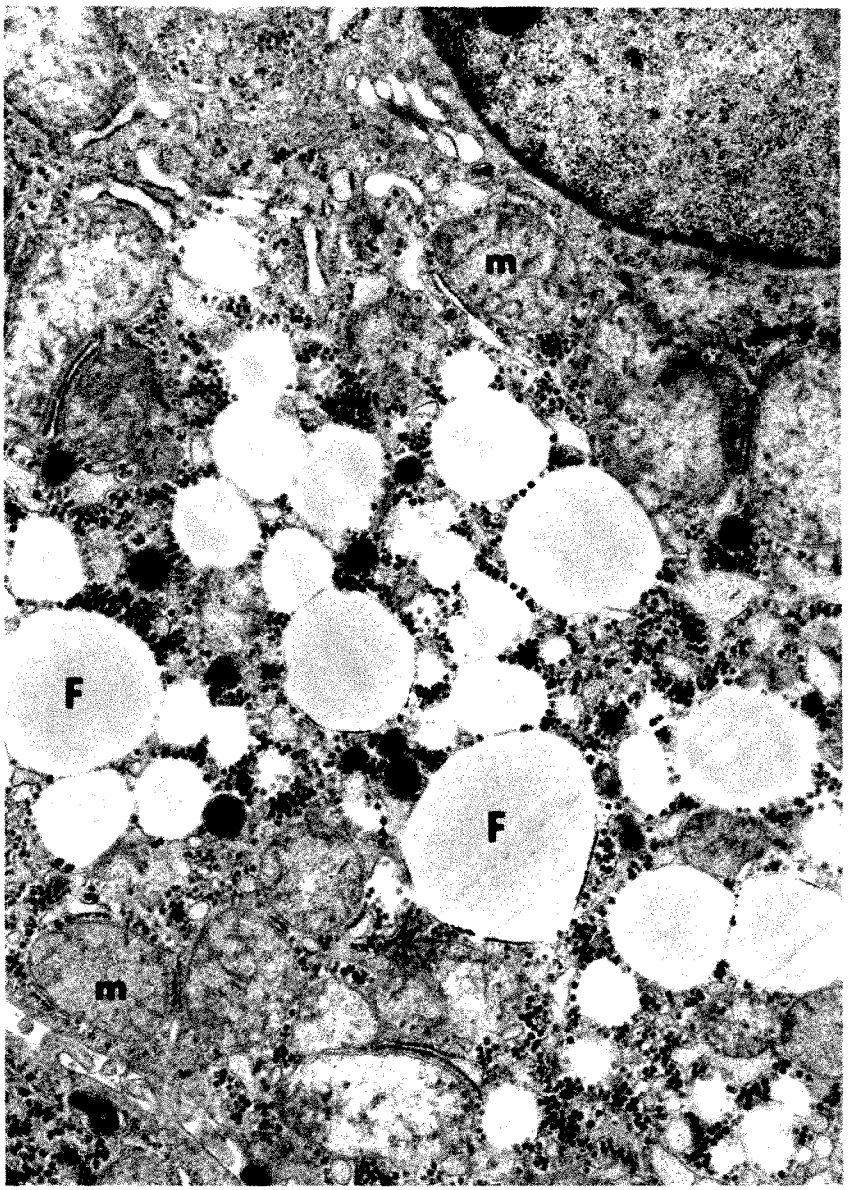

Fig. 7. Liver biopsy specimen of a 37-year-old woman (gravida 5, para 3, abortions 1) with recurrent microvesicular fatty change of pregnancy *(F)* but no preeclampsia. The fatty deposits are at least partially membrane bound with many nearby granules of glycogen. Mitochondria *(m)* are orthodox with somewhat irregular cristae but no cavitation. (Original transmission electron microscopic magnification, ×8000.)

This in turn may well be a consequence of genetic capacity. Clearly more work is needed on this aspect of these observations, especially with regard to possible correlations between the degree of ultrastructural change and the intensity or severity of the clinical syndrome.

One factor to consider with regard to genetics in the occurrence of preeclampsia is a tendency toward familial manifestations.[1] If there is a genetic component to preeclampsia, it is a singular one since the overt manifestations of whatever the underlying lesion or fault might be are seen only in women. Mother-to-daughter inheritance might be enhanced regularly if it were based on mitochondrial genetics, which are matrilineal[5] even though there is a definite regulatory or interactive role for nuclear deoxyribonucleic acid at very basic levels in the expression of the mitochondrial genome.[12] Such thoughts compel a possibly unasked

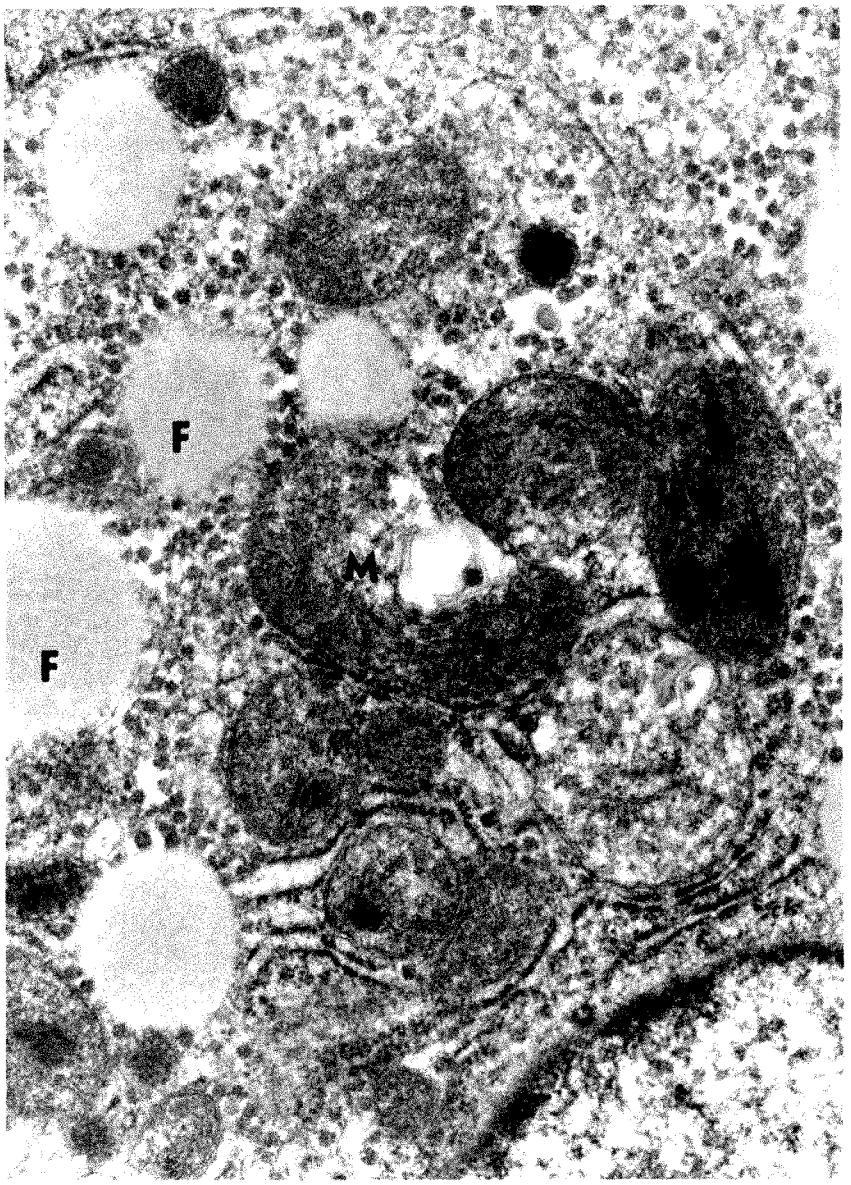

Fig. 8. Liver biopsy specimen of a 20-year-old primigravid woman with moderate preeclampsia; microvesicular fatty change *(F)* and mild central mitochondrial injury *(M)*. (Original transmission electron microscopic magnification, × 16,000.)

question: What are the metabolic expressions of mitochondrial lesions in the male offspring of mothers with preeclampsia?

This study is projective and qualitative, not quantitative. Additional studies are planned to determine more precisely the range, size, frequency, and internal constellation of the paranuclear complex. We also anticipate examining the manner by which and the extent to which the mitochondrial injuries we have described correlate with this structure that contains almost all of the mitochondria of uterine smooth muscle.

We thank Deborah Hollis for preparation of tissues for electron microscopy and Frank Moretta for the electron micrographs.

Absence of evidence of pulmonary maturity at amniocentesis in term infants of diabetic mothers

Emmanuel O. Ojomo, MD, and Donald R. Coustan, MD
Providence, Rhode Island

A total of 153 patients' charts were reviewed over a 6-year period to assess the results of the practice of amniocentesis for diabetic mothers at term (≥37 weeks' gestation) before elective induction/delivery. The numbers of cases with absent phosphatidylglycerol were determined at each specific gestational age at or near term. Phosphatidylglycerol was present in 130, and phosphatidylglycerol was absent in 23 at first amniocentesis sampling. A significant proportion (~21%) of those with gestational diabetes were phosphatidylglycerol–negative as late as 38 weeks' gestation. A similar proportion of overt diabetic patients were phosphatidylglycerol–negative as late as 39 weeks' gestation. These figures give the clinician some estimate of the likelihood of the absence of phosphatidylglycerol at or near term if amniocentesis is used before elective delivery in these patients. (Am J Obstet Gynecol 1990;163:954-7.)

Key words: Diabetes, amniotic fluid, phosphatidylglycerol, term

Many investigators have shown that maternal diabetes may adversely affect the process of fetal lung maturation.[1-7] Hyperglycemia and hyperinsulinemia have been implicated in delayed lung maturation in fetuses of diabetic mothers, but the precise mechanisms are still being investigated. Infants of diabetic mothers are known to have an increased incidence of respiratory distress syndrome (RDS).[8-12] Phosphatidylglycerol is a phospholipid that appears in significant amounts in amniotic fluid starting at about 36 to 37 weeks' gestation.[13-16] It has been used as a marker for lung maturation, and its appearance may be delayed in diabetic pregnancies with its absence being associated with RDS in some cases, despite a mature lecithin/sphingomyelin ratio.[17-19] For this reason, diabetic mothers who do not go into spontaneous labor at term routinely have amniocentesis done at many institutions, including ours, to determine the presence or absence of phosphatidylglycerol before elective induction/delivery. Our objective was to determine the frequency with which this practice yielded results that do not show pulmonic maturity.

Material and methods

A total of 153 charts of diabetic mothers who were delivered of infants at our center between February 1983 and January 1989 were reviewed. During that time period most pregnant women with diabetes were allowed to go into labor spontaneously, but those whose cervix was judged to be favorable for induction at or beyond 37 weeks' gestation were offered amniocentesis for assessment of fetal lung maturity and induction of labor if phosphatidylglycerol was present. Of our diabetic population 9.6% (153 of 1600) had amniocentesis for elective induction of labor or cesarean section at term during the study period; this included 7.3% (103/1415) of patients with gestational diabetes mellitus and 27% (50/185) of overt diabetic patients. The inclusion criterion was amniocentesis performed at ≥37 weeks' gestation. Patients were assigned to gestational diabetes (n = 103), overt diabetes type I (n = 27), and overt diabetes type II (n = 23) groups. Some were managed in our diabetic clinic and others by their private obstetricians.

All subjects had undergone transabdominal amniocentesis for fetal lung maturity before elective induction/delivery at term and were delivered in our hospital. When phosphatidylglycerol was absent, amniocentesis was repeated at a 7-day interval unless the patient declined repeat amniocentesis. Patients who had rupture of membranes before amniocentesis were excluded. Gestational age was determined on the basis of menstrual dates confirmed by ultrasonography in the majority of the patients. Elective delivery was deferred until phosphatidylglycerol was present.

We looked only at the first amniocentesis sample of each patient to eliminate bias that might be introduced by repetitive sampling. The numbers of cases with absent phosphatidylglycerol were determined at specific gestational ages or at near term.

Phosphatidylglycerol was determined by a two-

dimensional thin-layer chromatography method similar to that described by Kulovich et al.,[20] as described below. The sensitivity of the assay for phosphatidylglycerol is 0.025 mg/L. After centrifugation at 1600 rpm for 10 minutes, 5 ml of amniotic fluid supernatant in a mixture of chloroform and methanol (10/5, vol/vol) was centrifuged at 2000 rpm for 10 minutes on the day of collection. Specimens were stored at −20° C after centrifugation if specimens were to be run the next day. Cold acetone (0.75 ml) was used to precipitate the extracted phospholipids by centrifuging for 3 minutes at 2000 rpm. The extracted phospholipid (the unknown) was allowed to dry and then was reconstituted with 35 μl of chloroform. Precoated plates with silica gel 60 were used for the two-dimensional thin-layer chromatography. A standard that consisted of 0.025 mg/L of standard phosphatidylglycerol (P0514, Sigma, St. Louis) was used. Solvent I was made up of chloroform, methanol, glacial acetic acid, and water (65/25/8/4, vol/vol/vol/vol). Solvent II was made fresh each day of tetrahydrofuran, methylol, methanol, and 0.57 N ammonium hydroxide (50/37/8/5.25, vol/vol/vol/vol). Plates were removed, allowed to dry, placed in an iodine tank until the spots were visible, and then read.

Circulating glucose levels recorded during the third trimester were available for 61 subjects. Glucose levels were capillary whole blood samples measured on reflectance meters. Meter accuracy was verified by intermittent simultaneous capillary tube blood glucose measurements. Mean daily values were derived by averaging all measurements (fasting and 2 hours after each meal) obtained during the third trimester.

The group glucose means were derived by averaging all the means of the persons in each group, and were compared with the unpaired Student *t* test. Differences in prevalence of the absence of phosphatidylglycerol were compared with χ^2 analysis.

Results

A total of 130 diabetic mothers had phosphatidylglycerol present and phosphatidylglycerol was absent in 23 at first sampling at term. Of the 23 subjects with the absence of phosphatidylglycerol, 11 had gestational diabetes, seven had type I diabetes, and five had type II diabetes. The mean gestational age for the phosphatidylglycerol–negative group was 37.6 ± 0.7 weeks and that for the phosphatidylglycerol–positive group was 38.3 ± 1 weeks (p = NS). Phosphatidylglycerol was absent in ~26% of subjects at 37 weeks, ~20% at 38 weeks, ~4% at 39 weeks, and none at 40 weeks' gestation (Fig. 1).

When subjects were analyzed according to type of diabetes (Fig. 2), a significant proportion (~21%) of those with gestational diabetes were

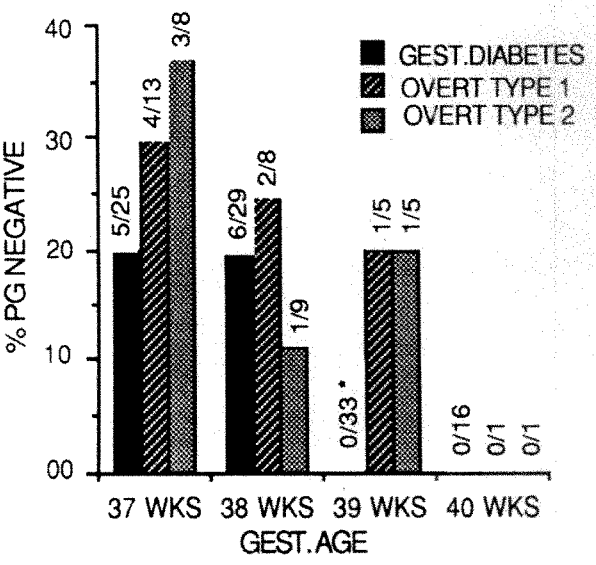

Fig. 2. Proportion of patients with various types of diabetes with absence of phosphatidylglycerol at each week of gestation near term. *PG*, phosphatidylglycerol.

phosphatidylglycerol–negative as late as 38 weeks' gestation. A similar proportion of women with overt diabetes were phosphatidylglycerol–negative at 39 weeks' gestation.

Comparison of the proportions of patients with gestational diabetes and overt diabetic mothers with the absence of phosphatidylglycerol did not show any significant difference until 39 weeks' gestation as shown in Fig. 2.

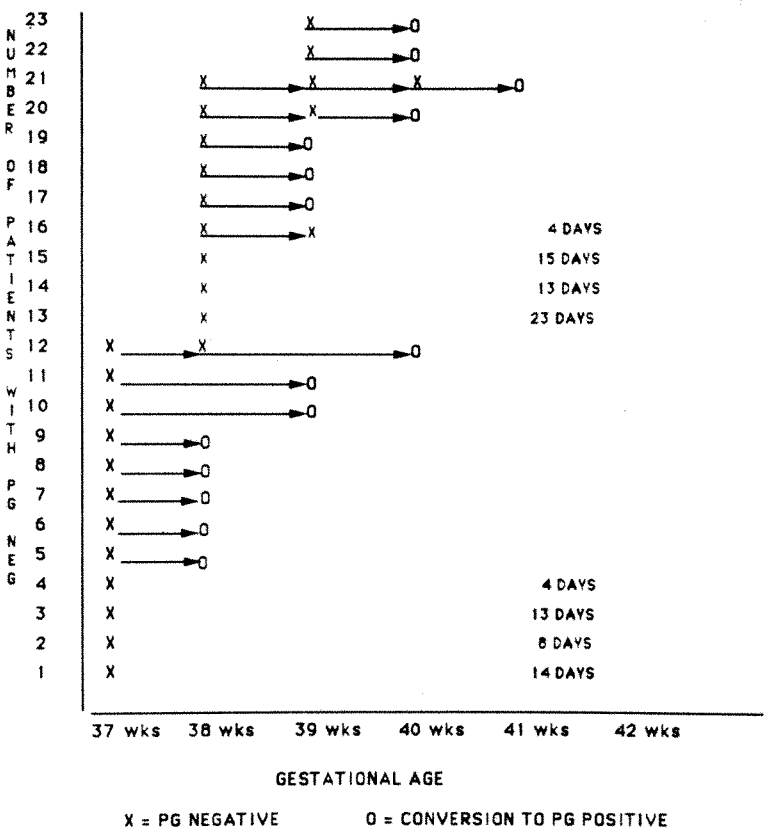

Fig. 3. Follow-up of subjects who were phosphatidylglycerol–negative at first sampling. Number of days denotes time elapsed from last amniocentesis to delivery. *PG*, phosphatidylglycerol.

Table I. Mean blood glucose levels in third trimester

Group	*No.*	*Mean*	*SD*
Phosphatidylglycerol negative	13	96.8 mg/dl	±9.9
Phosphatidylglycerol positive	48	100.6 mg/dl	±11.6

p = NS.

Of the 23 subjects with the absence of phosphatidylglycerol at or near term, phosphatidylglycerol developed in 15 with subsequent repeat amniocenteses. The other eight went into spontaneous labor and were delivered of infants before phosphatidylglycerol was shown to be present, but only two of these were delivered within 4 days of the documented absence of phosphatidylglycerol. The other six were delivered of infants within 8 to 23 days (Fig. 3). RDS did not develop in any infant.

We did not exclude diabetic mothers with other medical complications of pregnancy. However, 83 (64%) of the 130 diabetic mothers with amniotic fluid phosphatidylglycerol–positive and 15 (65%) of the 23 diabetic mothers with the absence of phosphatidylglycerol had no other medical conditions complicating their pregnancies. Twenty-six (20%) of the 130 diabetic subjects with positive phosphatidylglycerol and four (17%) of the 23 subjects with the absence of phosphatidylglycerol had infants ≥4000 gm. The degree of metabolic control of both groups was similar (Table I). When patients with gestational diabetes and overt diabetes who were phosphatidylglycerol–positive and phosphatidylglycerol–negative (and for whom glucose values were available) were compared separately, the degree of metabolic control was not significantly different.

Comment

Pregnancy duration is the most important factor in the determination of the presence or absence of phosphatidylglycerol in amniotic fluid at term in diabetic mothers. Our limited blood sugar data seem to support the findings of Ferroni et al.,[21] that diabetic blood glucose control had no significant effect on the amniotic fluid phospholipid levels. However, our subjects were generally in good metabolic control and none of those with the absence of phosphatidylglycerol had mean blood glucose levels ≥110 mg/dl. Landon et al.[22] had one White class B and two class D diabetic patients with

the absence of phosphatidylglycerol at 37 and 38 weeks' gestation, respectively, among subjects with mean capillary blood glucose levels ≥110 mg/dl, whereas in our study phosphatidylglycerol was absent in ~20% of overt diabetic patients as late as 39 weeks' gestation even though all available mean capillary blood glucose levels were ≤110 mg/dl. In our population of pregnant women with diabetes, a significant proportion of fetuses could not be documented to have pulmonic maturity at 38 to 39 weeks' gestation. We chose not to include the result of repetitive sampling on the same persons in our data anlaysis to avoid biasing a cross-sectional study with longitudinal data. Nevertheless, it should be noted that one person first sampled at 38 weeks' gestation did not convert to phosphatidylglycerol–positive status during weekly samplings until 41 weeks' gestation (Fig. 3).

Our study could not evaluate the prevalence of RDS among infants of diabetic mothers at term because patients were not electively delivered if phosphatidylglycerol was absent. Lack of phosphatidylglycerol is not invariably associated with RDS. Thus it should not be assumed that RDS will develop in 20% of infants of mothers with gestational diabetes or overt diabetes if electively delivered at 38 to 39 weeks' gestation. For clinicians who depend on phosphatidylglycerol for elective delivery in diabetic pregnancy, this compound may be absent in a significiant proportion of cases until 39 weeks' gestation is reached. The benefit of amniocentesis in well-controlled diabetic patients beyond 39 weeks' gestation remains debatable.

Liver histopathologic findings in women with sickle cell disease given prophylactic transfusion during pregnancy

Edward Yeomans, MD, Thomas W. Lowe, MD,
Edwin H. Eigenbrodt, MD, and F. Gary Cunningham, MD
Dallas, Texas

Forty women with a major sickle hemoglobinopathy (hemoglobin SS, SC, or S–β-thalassemia) were given red blood cell transfusions prophylactically during pregnancy. A mean of 13.6 units of erythrocytes per woman was given and none received more than 28 units. Direct-vision needle biopsy of the liver was performed in conjunction with cesarean section or puerperal sterilization. Although iron deposition in hepatocytes and Kupffer cells was identified commonly, neither cirrhosis nor widespread hepatocellular necrosis was found. We conclude that the risk of irreversible hepatic damage is negligible in women with sickle hemoglobinopathies who are given erythrocytes prophylactically during one pregnancy. (Am J Obstet Gynecol 1990;163:958-64.)

Key words: Sickle cell disease, pregnancy, prophylactic blood transfusions, liver histopathology

In 1971, investigators from Memphis[1] concluded that the risk of pregnancy for women with sickle cell disease was prohibitively high. Two years later, workers from Dallas[2] reported more favorable pregnancy outcomes although maternal morbidity and mortality still were significant. After the latter report from Parkland Hospital, we adopted a policy of prophylactic red blood cell transfusions for women with major sickle hemoglobinopathies (SS, SC, S–β-thalassemia). From our clinical experiences, which span nearly two decades,[3, 4] as well as those of others,[5] it is clear that both maternal and perinatal outcomes have improved dramatically with prophylactic transfusions. However, because these studies were not randomized and controlled, the singular importance of prophylactic transfusions was not established, and indeed, in a recently reported randomized investigation, it was concluded that such transfusions could be safely omitted.[6] Thus prophylactic red blood cell transfusions for pregnant women with sickle hemoglobinopathies remain controversial.[7] Undoubtedly a major factor militating against such therapy is transfusion-related morbidity, and one concern is that iron overload, or transfusion hemosiderosis, will cause irreversible damage to the liver or to other organs.[8] To better define this risk of erythrocyte administration, we performed intraoperative liver biopsy in 40 women with sickle hemoglobinopathies at the conclusion of a pregnancy during which each was transfused prophylactically.[3, 4]

Material and methods

Beginning in 1973, all pregnant women with a major sickle hemoglobinopathy (hemoglobin SS, SC, or S–β-thalassemia) who received prenatal care at Parkland Memorial Hospital were offered prophylactic red blood cell transfusions. As described in detail previously,[3, 4] packed red blood cells were given in volumes sufficient to achieve a hematocrit >25% and a percentage of cells containing sickle hemoglobin of ~50%. Because of the inherent risks of both transfusion therapy and the underlying disease, women participating in the protocol were counseled to consider permanent sterilization. Consent was obtained for a direct-vision needle biopsy to be performed either at the time of cesarean section or with puerperal sterilization done soon after vaginal delivery. All biopsies were performed within 4 weeks of the last transfusion, and in no case was percutaneous liver biopsy performed.

Immediately after biopsy, the histologic specimen was placed in formalin. Sections were cut, mounted, stained with hematoxylin-eosin, Masson trichrome, and Prussian blue, and graded microscopically in a systematic manner similar to that previously described[9] for the following features: (1) preservation or disruption of normal lobular and sinusoidal architecture; (2) hepatocellular necrosis, regeneration, iron deposition, and the presence of fat, lipofuscin, and bile inclusions; (3) portal tract fibrosis, cirrhosis, inflammation, and marginal disruption; (4) sinusoidal dilation and congestion,

erythrophagocytosis, and fibrosis; and (5) iron deposition in Kupffer cells. The stainable iron was graded as 0 if there were none or only rare granules in a few cells. Grade 1+ showed granules easily visible in 5% to 10% of cells. Grade 2+ had a grossly blue color and granules were present in about 40% of cells. Grade 3+ included specimens with most cells heavily laden with large granules.

Results

Forty women were studied, and, as shown in Table I, 22 had hemoglobin SS disease, 16 had SC disease, and two had sickle–β-thalassemia. Prophylactic transfusions in most patients were begun by midpregnancy and a mean of 13.6 (range 3 to 28) red blood cell units per woman was given. Before the index pregnancy, 18 of the 40 women had been transfused on one or more occasions, and five had received >10 units. None of these women had clinically evident liver disease at the time of biopsy; however, five of 18 with SS disease and one of 15 with SC disease had a serum transaminase level that exceeded 100 U/L (normal, 5 to 35 U/L) at some time during pregnancy. The one complication from liver biopsy was a small intrahepatic hematoma that resolved spontaneously in a woman with hemoglobin SC disease.

Each histologic specimen was evaluated and graded by one of us (E. H. E.) experienced in liver histopathology and the findings are summarized in Table II. The lobular architecture (identifiable portal tracts and central veins in their normal configuration) of the liver was undisturbed in each of the biopsy specimens examined. Mild abnormalities of the sinusoidal architecture (single-cell-thick plates radially oriented about central veins) were noted in slightly more than half (28 to 40) of the biopsy specimens (Figs. 1A and 1B). Single-cell hepatocyte necrosis, although encountered in more than half the biopsy specimens, was widely scattered and rare in any one specimen, and widespread necrosis was not identified (Fig. 2). Mild to moderate hepatocellular regeneration was also a prominent feature in most of the specimens. Evidence of extramedullary hematopoiesis was observed frequently.

Table II. Selected microscopic findings in liver biopsy specimens from 40 women with sickle hemoglobinopathies

Finding	*Degree of abnormality*			
	0	*1+*	*2+*	*3+*
Hepatocytes

Sinusoids				
Dilatation	7	13	14	6
Congestion	5	22	9	4
Erythrophagocytosis	1	39	—	—
Fibrosis	15	19	6	—
Erythrocyte sickling	17	9	13	1
Iron	7	20	10	3

Pathologic changes in the portal tracts were exceedingly uncommon. None of the 40 specimens showed evidence of cirrhosis or formation of fibrous septa, and in only one case was more than an insignificant increase in portal fibrosis noted. Widely scattered areas of acute or chronic inflammation were present in a minority of cases, and disruption of the limiting plate surrounding the portal areas was either focal or absent. No biopsy specimen showed evidence of acute or chronic hepatitis.

The hepatic sinusoids often showed changes but collectively did not represent significant liver injury. Sinusoidal dilatation was graded as marked (3+) in 6 of 40 specimens (Fig. 3), mild to moderate (1 to 2+) in 27 of 40, and absent in seven specimens. Congestion was severe (3+) in 4 of 40, moderate (1+ to 2+) in 31 of 40, and absent in only 6 of 40 biopsy specimens. Erythrophagocytosis by Kupffer cells was also a near-constant feature (Fig. 4). Of the red blood cells seen in the sinusoids, approximately half were sickled. Mild to

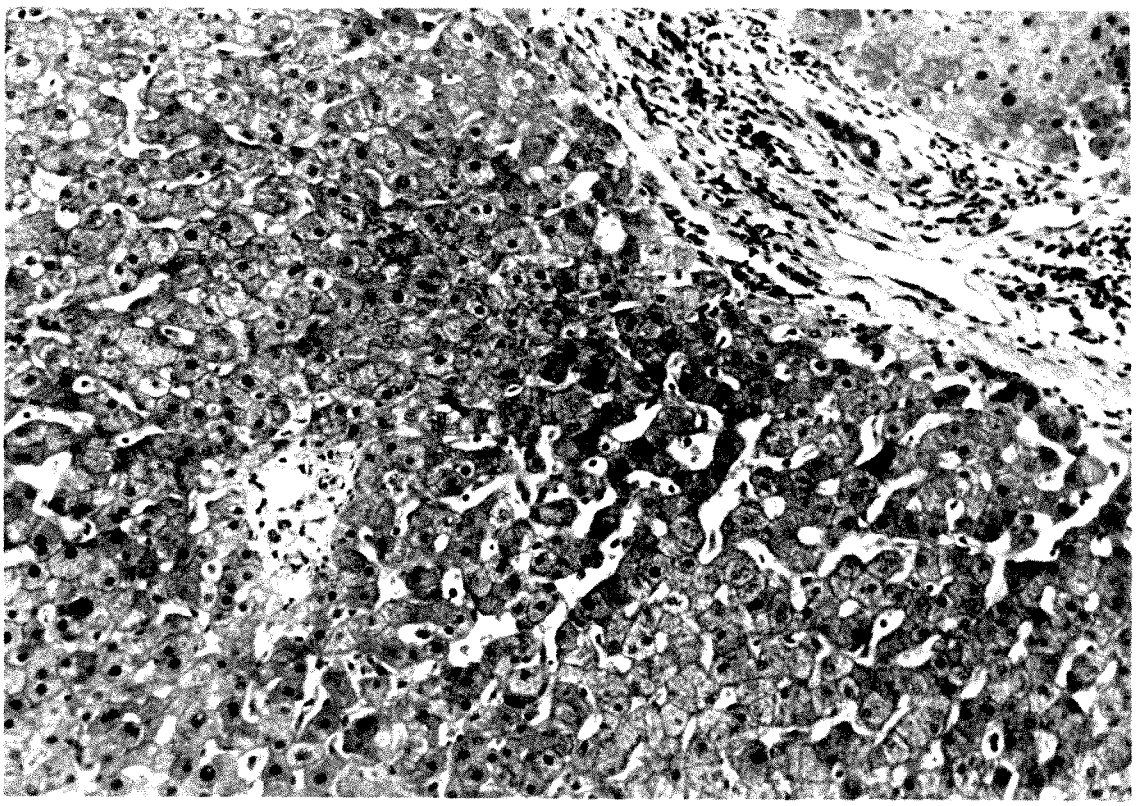

Fig. 1A. Portal tracts with intact limiting plates and single-cell-thick perioportal hepatocyte plates.

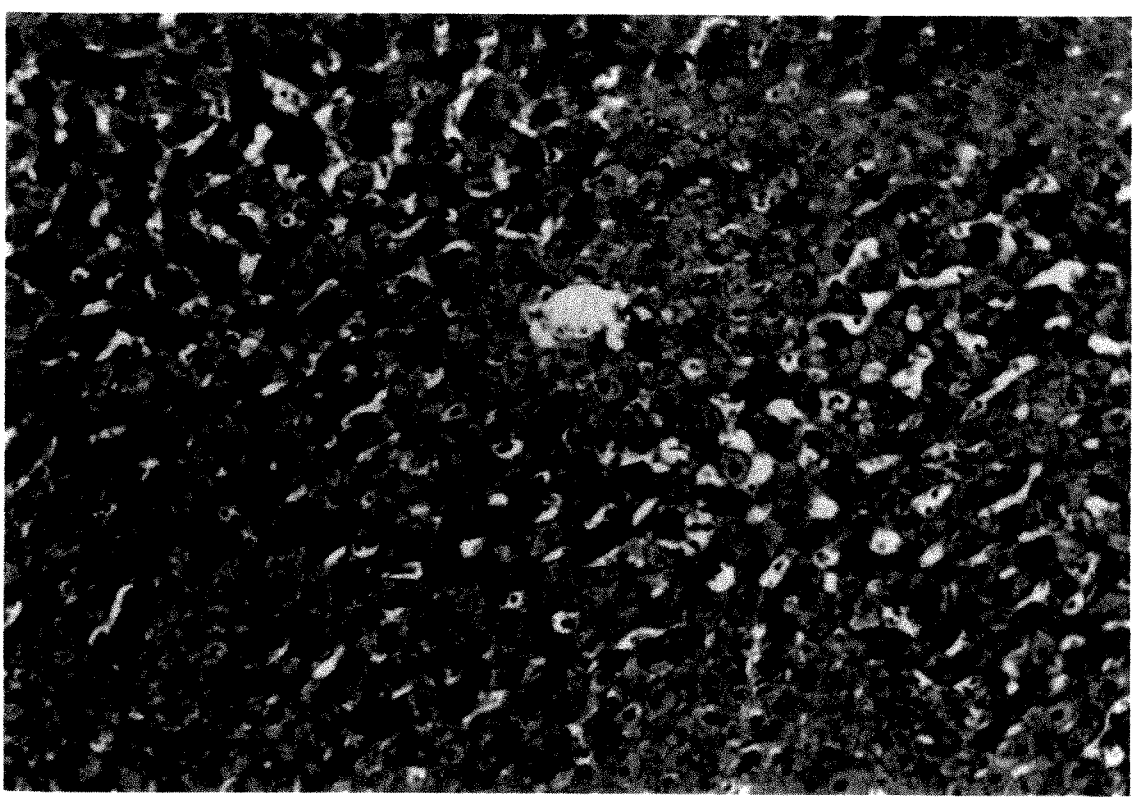

Fig. 1B. Centrilobular area showing central vein and sinusoidal dilatation without prominent congestion. Note single-cell-thick plates and absence of hypoxic injury (atrophy).

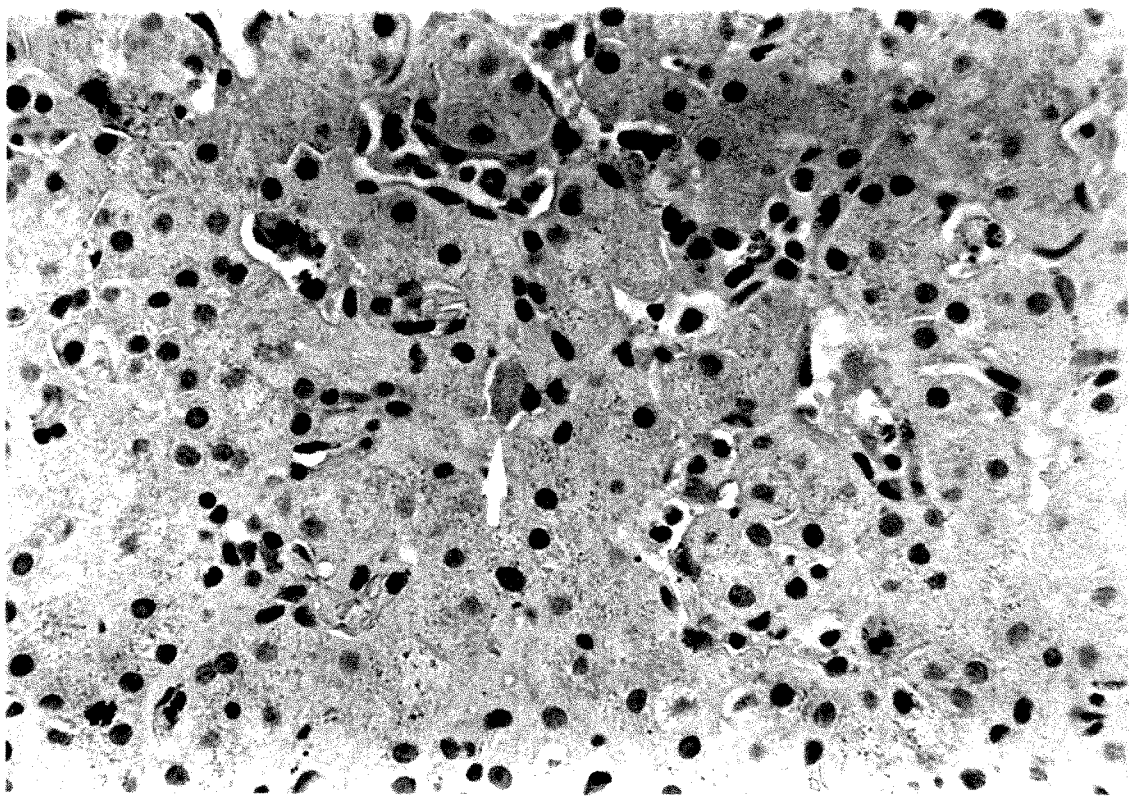

Fig. 2. Single-cell necrosis. *Arrow* indicates an acidophilic (Councilman-like) body.

moderate sinusoidal reticular fibrosis was present in slightly more than half the specimens.

Stainable iron was increased in each biopsy specimen. In a third of the specimens, iron deposition in hepatocytes exceeded that in Kupffer cells (Fig. 5), while the reverse was true in another third. The remaining third demonstrated nearly equal distribution of iron between the two sites. Only 2 of 40 specimens showed large granules of iron (3+) in most of the hepatocytes.

Comment

Schafer et al.[8] reported liver biopsy results from 10 of 15 adults with transfusion-dependent anemia who, over a 4-year period, were transfused with 80 to 210 (mean, 120) units of blood. They described "striking hemosiderosis" with iron deposition in both hepatocytes and Kupffer cells, and there was focal portal fibrosis and inflammation in the majority of cases. In contrast, the 40 pregnant women with sickle hemoglobinopathies described here were transfused prophylactically with an average of 13.6 units of red blood cells and none received more than 28 units. None of these asymptomatic women had evidence on liver biopsy of widespread necrosis, extensive inflammation, fibrous septa formation, or cirrhosis. Conversely, sinusoidal dilatation, erythrophagocytosis, and intrasinusoidal sickling usually were seen. Because normal pregnancy causes no definite changes in liver morphologic features, the histologic findings described here cannot be attributed to pregnancy. It seems likely that the difference in the number of units transfused and consequently in iron load is responsible for the minimal pathologic findings in our patients compared with those reported by Schafer et al.[8]

Histopathologic data derived from the liver biopsy specimens reported here represent the largest series of patients, pregnant or nonpregnant, in the literature to date and thus contribute significantly to the knowledge of liver involvement in sickle hemoglobinopathies. On the basis of 12 percutaneous liver biopsies, Rosenblate et al.[10] implied that all patients with sickle cell disease had similar hepatic abnormality and showed widely dilated and congested sinusoids, erythrophagocytosis by Kupffer cells, and parenchymal atrophy in the centrilobular regions. These changes were relatively minimal and amenable to regeneration without chronic destructive changes and were thought to be related to so-called sickle cell crises. Rosenblate et al.[10] confirmed the findings of earlier studies, which suggested that sinusoidal obstruction that was secondary to engorged Kupffer cells and sickled erythrocytes led to anoxia distal to the obstruction. Our patients usually did not have sickling episodes because they were given prophylactic transfusions, yet they showed similar histologic features with

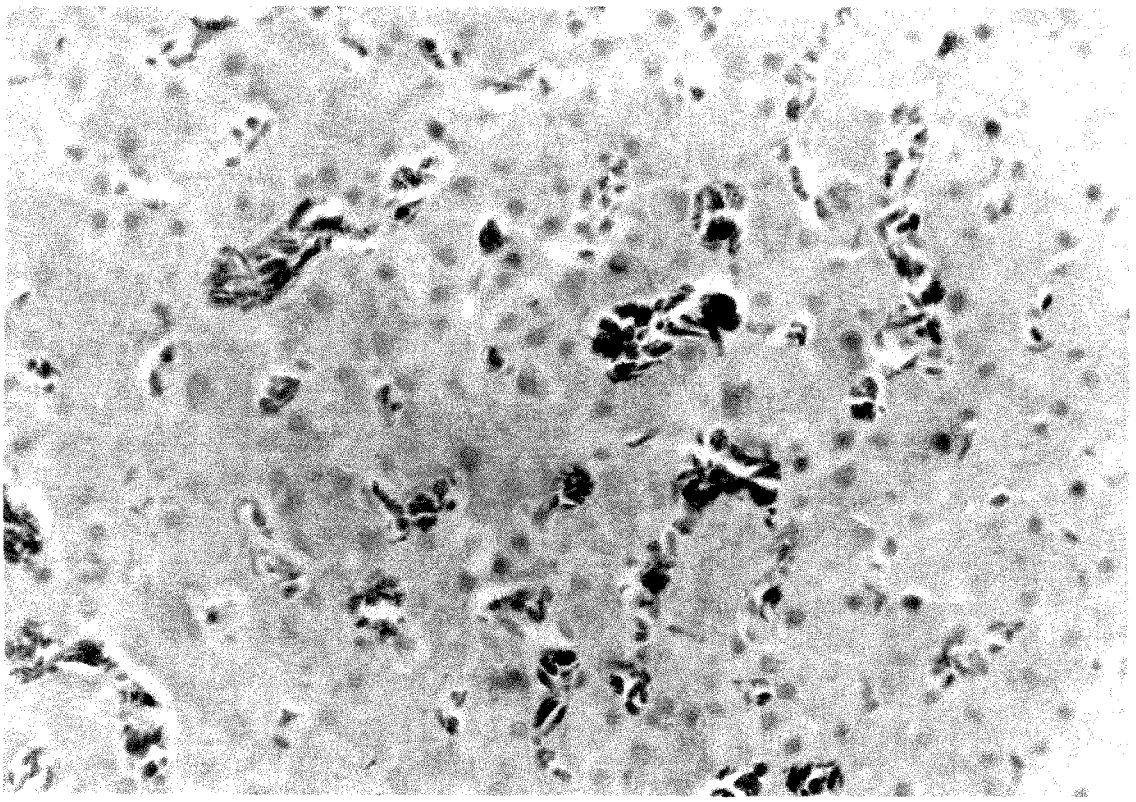

Fig. 3. Sinusoidal dilatation and congestion. Although the process is marked in this photomicrograph, there is no evidence of anoxic damage. Note the number of sickled erythrocytes.

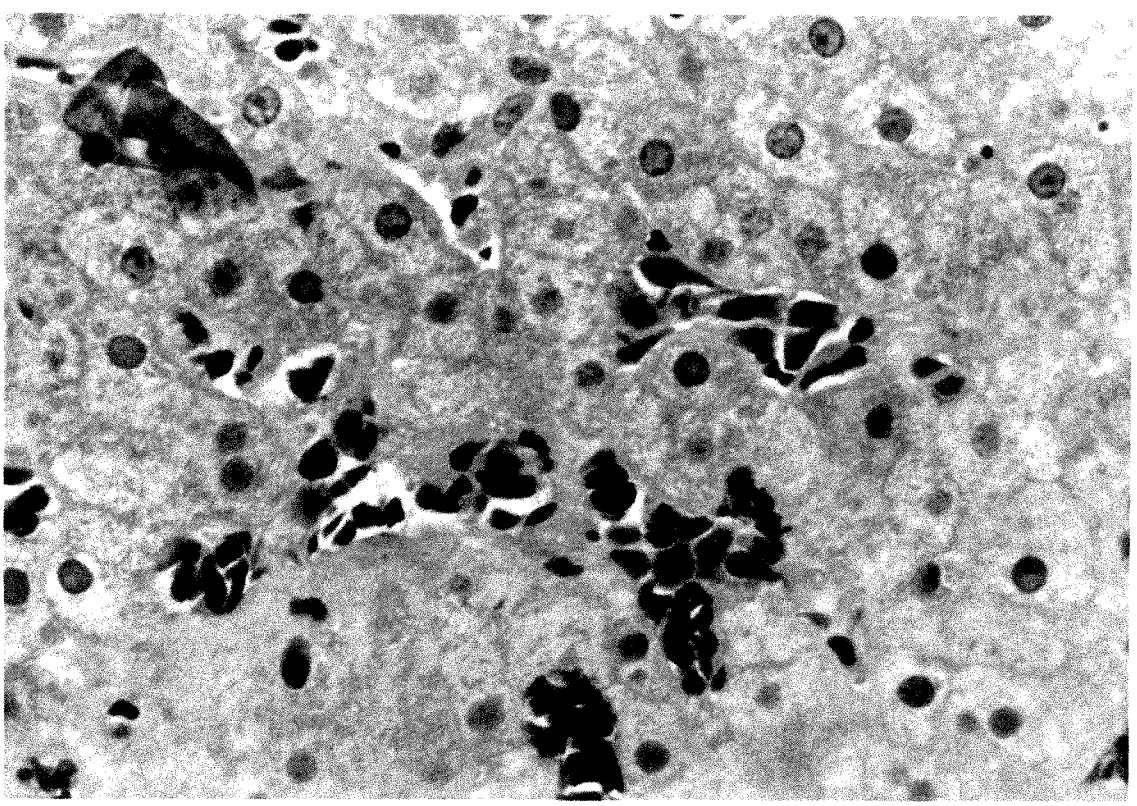

Fig. 4. Erythrophagocytosis. Shown are Kupffer cells with ingested erythrocytes.

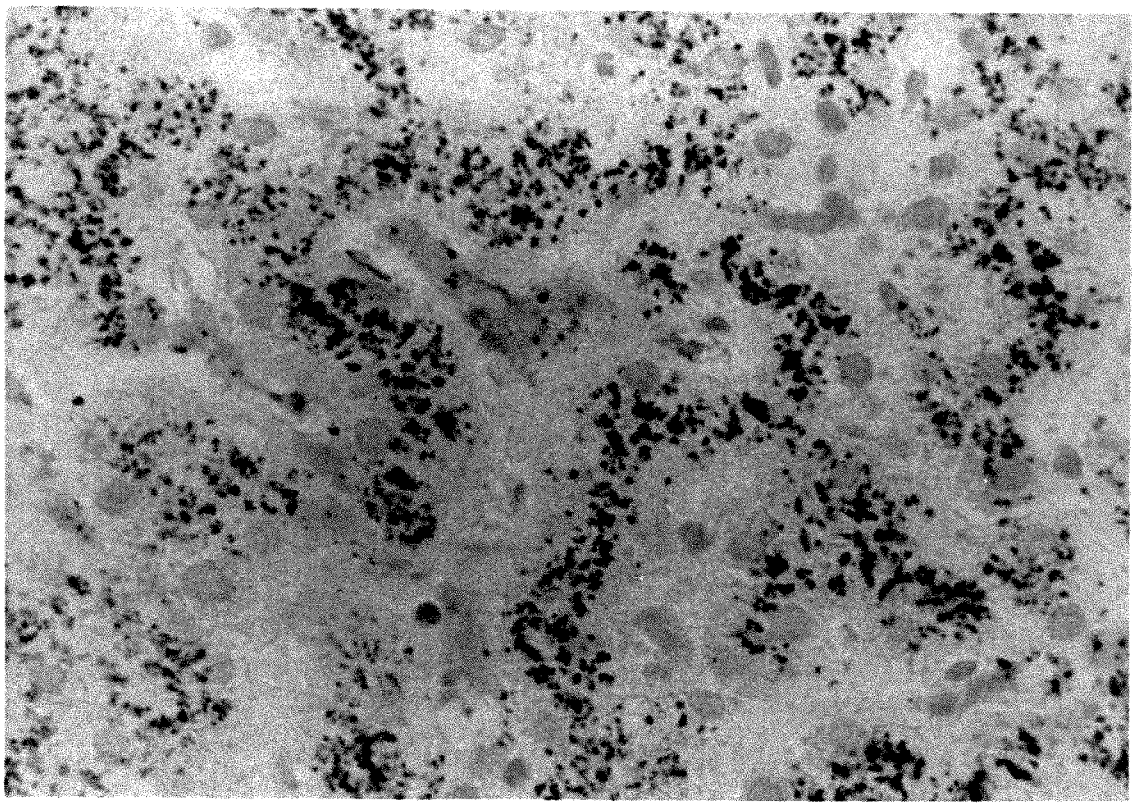

Fig. 5. Prussian blue stain for iron. The iron is predominantly present in the hepatocytes and is seen as darkly staining granules.

the exception that centrilobular atrophy was not observed.

There is evidence that other, more significant pathologic findings in sickle cell patients usually are caused by superimposed illnesses. In an autopsy study spanning more than 90 years, Bauer et al.[11] concluded that the spectrum of otherwise unexplained liver injury in patients with sickle cell disease most likely resulted from sinusoidal obstruction and anoxia. However, 44 of their 70 patients had liver disease attributed to a variety of complicating illnesses, including viral hepatitis, sepsis, shock, toxin exposure, hemochromatosis, and cardiac cirrhosis. Johnson et al.[12] performed liver biopsies in 11 patients with sickle cell disease who had persistently abnormal liver function tests and concluded that all had other complicating illnesses. This group[13] later compared histologic findings from 19 liver biopsy specimens with 32 autopsy specimens and found ischemic necrosis almost exclusively in the postmortem material. They noted intrasinusoidal sickling and Kupffer cell erythrophagocytosis in almost all specimens but found no correlation between these histologic changes and the degree of transaminase elevation. Additionally, although perivenular necrosis would be expected if sinusoidal obstruction led to hypoxic or anoxic liver injury, it was notably absent.

Importantly, Omata et al.[13] performed incidental intraoperative liver biopsy in five patients at the time of cholecystectomy and found no significant morphologic changes other than intrasinusoidal sickling and Kupffer cell erythrophagocytosis. This small group of control patients most closely approximates the 40 otherwise asymptomatic women described here. Finally, Mills et al.[14] reported findings from 13 liver biopsies performed in patients with sickle cell disease and confirmed that sickled red blood cells, sinusoidal distention, and Kupffer cell erythrophagocytosis were found in all to some degree but did not correlate with evidence of hepatocellular damage or with clinical features.

We conclude, at least for a single pregnancy, that prophylactic erythrocyte transfusions do not lead to irreversible hepatic damage. Reversible changes in liver histologic characteristics did not correlate with the number of units transfused. Even though there was evidence of hepatic iron overload with stainable iron present to some degree in every biopsy specimen, the associated histopathologic changes were no more than those previously reported in patients with sickle cell disease. Unfortunately, we cannot exclude longer-term adverse effects of prophylactic transfusions, for example, chronic hepatitis or other infectious complications. Because of this, we continue to advocate lim-

iting the use of transfusion therapy to a single pregnancy.

Comparison of a rapid enzyme-linked immunosorbent assay test and the Gram stain for detection of group B streptococcus in high-risk antepartum patients

Craig V. Towers, MD, Thomas J. Garite, MD, Wendy W. Friedman, MT(ASCP), Richard A. Pircon, MD, and Michael P. Nageotte, MD

Long Beach and Irvine, California

Early-onset neonatal sepsis with group B streptococci is a major problem in the management of high-risk obstetrics. Intrapartum treatment of the colonized mother reduces neonatal acquisition; however, many high-risk patients are delivered before culture results are available. This study prospectively evaluated a new enzyme-linked immunosorbent assay and the Gram stain for their accuracy in rapid detection of group B streptococci in 131 high-risk patients. Twenty positive cultures for group B streptococci were identified in the study population and were used as the control for test comparisons. The enzyme-linked immunosorbent assay test was 60% sensitive, whereas the Gram stain was 45% sensitive. The enzyme-linked immunosorbent assay showed an increase in sensitivity as the colony count increased; however, two cases of severe neonatal sepsis occurred in patients with low colony counts and both had enzyme-linked immunosorbent assay negative results. In conclusion, the need for a rapid sensitive test for group B streptococci detection still exists. (Am J Obstet Gynecol 1990;163:965-7.)

Key words: Group B streptococci, ELISA, Gram stain, sensitivity

Group B streptococci are the leading cause of neonatal sepsis with 12,000 to 15,000 cases reported each year.[1] Early-onset infection usually occurs within the first 24 hours of life and can lead to pneumonia, septicemia, meningitis, septic shock, and in some cases death.[1] The transmission of group B streptococci to the infant with early-onset disease is thought to result from intraamniotic infection or with passage through the birth canal.[2] It has been shown that if the mother is treated with antibiotics before delivery neonatal outcome is improved by apparent ablation of vertical transmission.[3, 4]

Group B streptococcal colonization ranges from 5% to 30% of all pregnant women.[5] Attempts to obtain cultures from all pregnant women, with treatment of those with positive results has not been cost effective and recolonization is common.[6, 7] In addition, 80% of serious group B streptococcal infections occur in the premature infant.[8, 9] Therefore attention has focused primarily on obtaining cultures from high-risk patients with treatment before delivery if possible.[10] Unfortunately, many of these high-risk patients are delivered before culture results are available.

The purpose of this study was to prospectively evaluate a new rapid enzyme-linked immunosorbent assay (ELISA) test (Equate, marketed by Binax, South Portland, Me.) and the Gram stain to determine if either test was sensitive enough to use in the management of these high-risk patients.

Material and methods

All patients for the study were prospectively identified from Jan. 1, 1989, to July 30, 1989, at Memorial Womens Hospital of Long Beach. In every patient three swab samplings were obtained. The sampling technique was the same for each swab and from patient to patient. This technique would start at the cervix and then sweep the vaginal walls and introitus on removal in an attempt to sample the entire birth canal. Each case had three tests performed: the ELISA test, a Gram stain, and a culture for group B streptococci on selective medium; a separate swab was used for each test. The culture results were used as the prevalence rate to which the two rapid tests were compared. All three tests were performed as they were received by the laboratory; batching of tests did not occur.

The culture was performed with a three-quadrant technique. The swab was applied to the first quadrant and then a wire loop was passed through this quadrant to inoculate the second and third quadrants. Culture results were reported as light growth if growth

Table III. Comparison of ELISA and Gram stain results with amount of group B streptococcal growth in culture

Culture growth	*No. of cases with group B streptococci*	*No. of positive ELISA results*	*No. of positive Gram stains*
Light	9	4 (44%)	4 (44%)
Moderate	6	4 (67%)	3 (50%)
Heavy	5	4 (80%)	2 (40%)
TOTAL	20	12	9

Light growth = colony count <10,000 cfu; moderate growth = colony count 10,000 to 100,000 cfu; heavy growth = colony count >100,000 cfu.

was confined to the first quadrant (colony count <10,000 cfu). Heavy growth was reported if growth reached the third quadrant (colony count >100,000 cfu) and moderate growth was reported if growth occurred in the first and second quadrants only (colony count 10,000 to 100,000 cfu).

The ELISA test was performed as described in the manufacturer's instructions. A positive and negative control was run with each test sample. A critical part of the test is the washing step that requires at least five forceful washings of the test tube with free-running tap water. Additional washings were acceptable and each test case had from five to eight washes performed. A positive test for group B streptococci results in a distinct blue color whereas a negative test is colorless. The results of the ELISA test were blinded from the clinician until completion of the entire study.

The ELISA test instructions state that the reliability of the test can be seen for up to 2 weeks after collection. Therefore a few swabs were saved and were retested at 7 and 14 days. The results of these repeat tests were compared with the initial test results.

The Gram stain was performed in the usual fashion and the presence of any gram-positive cocci indicated a positive result.

Results

One hundred thirty-one high-risk patients were evaluated. The mean gestational age was 30.4 weeks (range, 22 to 40 weeks). Five cases were ≥36 weeks of gestation and had prolonged premature rupture of membranes with no prenatal care. The remaining 126 cases were ≤35 weeks' gestation with either preterm premature rupture of the membranes (80 cases), premature labor (37 cases), or premature cervical dilatation (9 cases). None of the 131 patients received antibiotics before swabs for the study were obtained.

There were 20 cases with a positive group B streptococcal culture result, an incidence of 15%. The results of the ELISA and Gram stain in comparison with these 20 positive culture cases are seen in Table I. The sensitivity, specificity, and positive and negative predictive values of each rapid test are seen in Table II. Neither test was highly sensitive in identifying group B streptococcal colonization. However, the ELISA was statistically more specific and had a better positive predictive value.

In evaluation of each rapid test in regard to sensitivity with relation to the colony count (Table III), it was found that the sensitivity of the ELISA increased as the colony count increased. The sensitivity of the Gram stain did not change as the colony count increased.

Sixty patients (46%) were delivered of their infants <24 hours after admission and before culture results were available. Eight of these 60 patients (40% of the positive group B streptococcal cultures) were colonized with group B streptococci. The ELISA and the Gram stain were each positive for group B streptococci in five of these eight cases. Therefore 37% of group B streptococci–positive patients who were delivered before culture results were known would have been missed if treatment was based only on these rapid tests.

The ELISA test kit requires the use of a dry swab. The majority of microbiologic tests, however, use a wet swab. Eighty-five cases had both a wet and a dry swab run simultaneously and the results were the same in every case. In addition, six cases had repeat tests run 7 to 14 days after the initial test. Three cases were positive for group B streptococci and three were neg-

ative. The results of the repeat tests were identical to the initial test result in every case.

All 131 cases were evaluated through delivery. The 12 patients with positive group B streptococcal cultures who were not delivered within 24 hours were all treated with antibiotics and no group B streptococcal infections occurred. There were no cases of group B streptococcal infection in the 111 cases with negative culture results. Of the eight patients with positive group B streptococcal cultures who were delivered within 24 hours, four were treated before delivery because of maternal fever and no group B streptococcal infections occurred. The remaining four patients did not receive treatment, and in two of these infants group B streptococcal sepsis developed and the infants ultimately died. One of these was a 26-week gestation with extreme prematurity as a factor; the other was a 32-week gestation. The culture revealed light growth of group B streptococci in both cases.

Comment

We evaluated the new Equate ELISA test for its ability to identify group B streptococci colonization in high-risk pregnant patients. Unfortunately, the test was only 60% sensitive. If the only concerns were for patients with moderate or heavy growth by culture, the sensitivity for the ELISA increased. However, 20% to 33% of patients with positive group B streptococcal cultures would still have been undetected. In addition, the two infants with documented group B streptococcal sepsis occurred in cases with light growth by culture when both the ELISA and the Gram stain were negative.

The results of the Gram stain were no different. If treatment was isolated to only those patients with a positive Gram stain, up to 50% of patients with group B streptococci would have been undetected and a large number of patients would have received treatment when it was not needed. As seen in our data, the Gram stain yields a large number of false-positive results. This is most likely because of the numerous other gram-positive organisms that can be found in the female genital tract other than group B streptococci. We have no explanation for the significant number of false-positive ELISA results that were obtained.

When the study was first initiated, the senior medical technician (W. W. F.) performed the ELISA test. The sensitivity of the test for identifying group B streptococci in her hands was 75%. As the study progressed, other medical technicians were allowed to perform the test (as would occur in the everyday setting) and the sensitivity dropped to only 43%.

The ELISA test kit requires the use of a dry swab; however, the use of a wet swab did not alter the results in this study. In addition, it appears that the accuracy of the test does remain stable for up to 7 to 14 days after its collection as stated in the product information package.

Because many patients with positive group B streptococcal test results are delivered before culture results are available, the need still exists for a rapid sensitive test. One management option is to treat all high-risk patients until the culture results are known. However, this would result in the treatment of many patients in whom treatment might not be indicated, possibly resulting in the development of resistant organisms. We agree with the treatment plan of Minkoff and Mead,[11] which proposes antibiotic therapy only for high-risk patients if delivery is inevitable before culture results are known. This proposal avoids unnecessary treatment of stable patients when time allows for the culture results but at the same time treats all patients who are colonized with group B streptococci but who deliver too quickly. We do not recommend the use of these rapid tests as the only basis for treatment in high-risk patients because of their poor sensitivity. Therefore the evalution of rapid tests for group B streptococcal detection should continue until a sensitive test is ultimately produced.

Amniotic fluid glucose concentration: A rapid and simple method for the detection of intraamniotic infection in preterm labor

Roberto Romero, MD, Carlos Jimenez, MD, Ajay K. Lohda, MD, Jose Nores, MD, Shuichi Hanaoka, MD, Cecilia Avila, MD, Robert Callahan, BS, Moshe Mazor, MD, John C. Hobbins, MD, and Michael P. Diamond, MD

New Haven, Connecticut

The purpose of this study was to determine whether amniotic fluid glucose concentrations is of value in the rapid diagnosis of intraamniotic infection. Amniocenteses were performed in 168 patients with preterm labor and intact membranes. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as *Mycoplasma* species. The prevalence of positive amniotic fluid cultures was 13.6% (23/168). Patients with positive amniotic fluid cultures for microorganisms had significantly lower median amniotic fluid glucose concentrations than patients with negative amniotic fluid cultures (median 11 mg/dl, range 2 to 30 mg/dl vs median 28 mg/dl, range 3 to 74, respectively; $p < 0.001$). Amniotic fluid glucose concentrations below 14 mg/dl had a sensitivity of 86.9% (20/23), a specificity of 91.7% (133/145), a positive predictive value of 62.5% (20/32), and a negative predictive value of 97.8% (133/136) in the detection of a positive amniotic fluid culture. Amniotic fluid glucose determination is a rapid, sensitive, inexpensive, and simple test for the detection of intraamniotic infection in women with preterm labor and intact membranes. (AM J OBSTET GYNECOL 1990;163:968-74.)

Key words: Glucose, intraamniotic infection, chorioamnionitis, preterm labor, prematurity, Gram stain, amniotic fluid

Strong evidence supports an association of intraamniotic infection with preterm labor and delivery.[1] Patients in preterm labor with intact membranes and positive amniotic fluid cultures are more likely to have clinical chorioamnionitis and fail to respond to tocolysis.[1, 2] Furthermore, neonates born to women with positive amniotic fluid cultures are at an increased risk for infectious complications.[2]

The early diagnosis of intraamniotic infection is a desirable clinical goal. However, clinical signs of infection are insensitive and will detect only 12% of patients with positive amniotic fluid cultures in women with preterm labor and intact membranes.[2] While amniotic fluid cultures are widely used to assess the microbiologic state of the amniotic cavity, results are not immediately available and may take up to 5 days. Rapid methods for the detection of infection, such as the Gram stain and the acridine orange stain of amniotic fluid, are insensitive, detecting only 50% to 60% of all intraamniotic infections.[3, 4] Other tests, such as gas-liquid chromatographic analysis of organic acids in amniotic fluid, require expensive equipment and trained personnel and are not available in most medical centers. Thus there is a need for a sensitive, simple, and rapid test for the detection of intraamniotic infection.

A decreased glucose concentration in several body fluids (i.e., cerebrospinal fluid, pleural fluid, and synovial fluid) has been used for the diagnosis of infection.[5-7] The purpose of this study was to determine whether amniotic fluid glucose concentration could be of value in the diagnosis of intraamniotic infection. The value of amniotic fluid glucose concentration in the diagnosis of intraamniotic infection was first suggested by Dr. Brian Kirshon (personal communication, 1989).

Material and methods

Patient population. The study population consisted of 168 consecutive patients who were admitted to Yale–New Haven Hospital with the diagnosis of preterm labor and intact membranes from March 3, 1988, to May 26, 1989, and who underwent amniocenteses for evaluation of the microbiologic status of the amniotic fluid. Patients with known abnormal glucose tolerance test results or with overt diabetes mellitus were excluded. Preterm labor was defined as the presence of

regular uterine contractions with a frequency of at least two every 10 minutes. Rupture of membranes was excluded by testing for pooling, Nitrazine paper reaction, and ferning. Ritodrine, terbutaline, or magnesium sulfate was administered intravenously for tocolysis after amniocentesis. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 5 cm or delivery occurred.

Retrieval of amniotic fluid. In all cases amniotic fluid was retrieved by transabdominal amniocentesis, which was performed under ultrasonographic guidance.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for *Mycoplasma* species (*Mycoplasma hominis* and *Ureaplasma urealyticum*), according to methods previously described.[4]

Gram stain examination. Gram stain examinations were performed by using commercial reagents (crystal violet, saffranin, and Gram's iodine [Difco Laboratories, Detroit]) under standard conditions. Stained slides were then examined by trained technologists, and the presence or absence of microorganisms was noted. The results of the Gram stain examinations were shared with the clinicians. Patients with negative Gram stain examinations for bacteria were given tocolysis. Patients with positive Gram stain examination of amniotic fluid for bacteria were given parenteral antibiotics and allowed to labor. A positive Gram stain for bacteria was an indication for discontinuing tocolysis.

Amniotic fluid glucose determinations. Amniotic fluid was centrifuged at 700 *g* for 10 minutes at 4° C and stored at −70° C until assayed. Glucose analysis was performed by the glucose oxidase method with a Beckman glucose analyzer. Samples were run in duplicate. Results were not available for patient management. The coefficient of variation was 5%.

Criteria for diagnosis of chorioamnionitis and neonatal sepsis. Intraamniotic infection was defined as the presence of a positive amniotic fluid culture.[1] Clinical chorioamnionitis was defined according to the criteria proposed by Gibbs et al.[8] Neonatal sepsis was diagnosed by the presence of a positive culture of blood, urine, or cerebrospinal fluid.

Statistical analysis. A Mann-Whitney test was used to compare amniotic fluid glucose concentrations between infected and noninfected patients. A receiver operator characteristic curve analysis was conducted with the program True Epistat (Epistat Services, Richardson, Tex.). Diagnostic indices (sensitivity, specificity, and positive and negative predictive values) for the detection of a positive amniotic fluid culture were calculated for both the Gram stain and amniotic fluid glucose.

Results

The criteria for inclusion into this study were met by 168 patients, 54.1% (91/168) of whom went on to have a preterm delivery. The remainder were delivered at term. The prevalence of positive amniotic fluid cultures was 13.6% (23/168).

Fig. 1 displays amniotic fluid glucose concentrations according to culture results. Patients with positive amniotic fluid cultures for microorganisms had significantly lower median amniotic fluid glucose concentrations than patients with negative amniotic fluid cultures (median 11 mg/dl, range 2 to 30 mg/dl vs median 28 mg/dl, range 3 to 74, respectively; $p < 0.001$, Mann-Whitney test).

To describe the relationship between the sensitivity (true-positive rate) and the false-positive rate for different values of amniotic fluid glucose in the detection of a positive amniotic fluid culture, a receiver operator characteristic curve was constructed. Fig. 2 displays the receiver operator characteristic curve (area under the curve 0.93; SE 0.03; z 14.1; $p < 0.001$). The curve is well above the 45-degree line, indicating that an abnormal test result (reduced amniotic fluid glucose concentration) increases the probability of a positive amniotic fluid culture. As with any other diagnostic test, there is a trade-off between the sensitivity (true-positive rate) and the false-positive rate (100 − Specificity). We chose to present the diagnostic indices using a cutoff at 14 mg/dl, as this value seems to represent a reasonable compromise between a true-positive and a false-positive rate.

A glucose level below 14 mg/dl had a sensitivity of 86.9% (20/23), a specificity of 91.7% (133/145), a positive predictive value of 62.5% (20/32), and a negative predictive value of 97.8% (133/136). On the other hand, the diagnostic indices for the Gram stain examination of amniotic fluid were: sensitivity of 65.2% (15/23), specificity of 99.3% (144/145), positive predictive value of 93.7% (15/16), and negative predictive value of 94.7% (144/152).

When the Gram stain and glucose level (below 14 mg/dl) were used in combination (either test result considered abnormal), the diagnostic indices were sensitivity of 86.9% (20/23), specificity of 91% (132/145), positive predictive value of 60.6% (20/33), and negative predictive value of 97.8% (132/135).

There were 131 patients with negative Gram stains and glucose concentrations above 14 mg/dl. Three had positive amniotic fluid cultures (two with *Ureaplasma urealyticum* and one with *Gardnerella vaginalis*). All three patients failed to respond to intravenous tocolysis and were delivered of preterm neonates.

Table I displays the clinical data of the 12 patients with amniotic fluid glucose concentrations of <14 mg/dl and negative amniotic fluid cultures for bacteria and *Mycoplasma* species. Although all of these patients

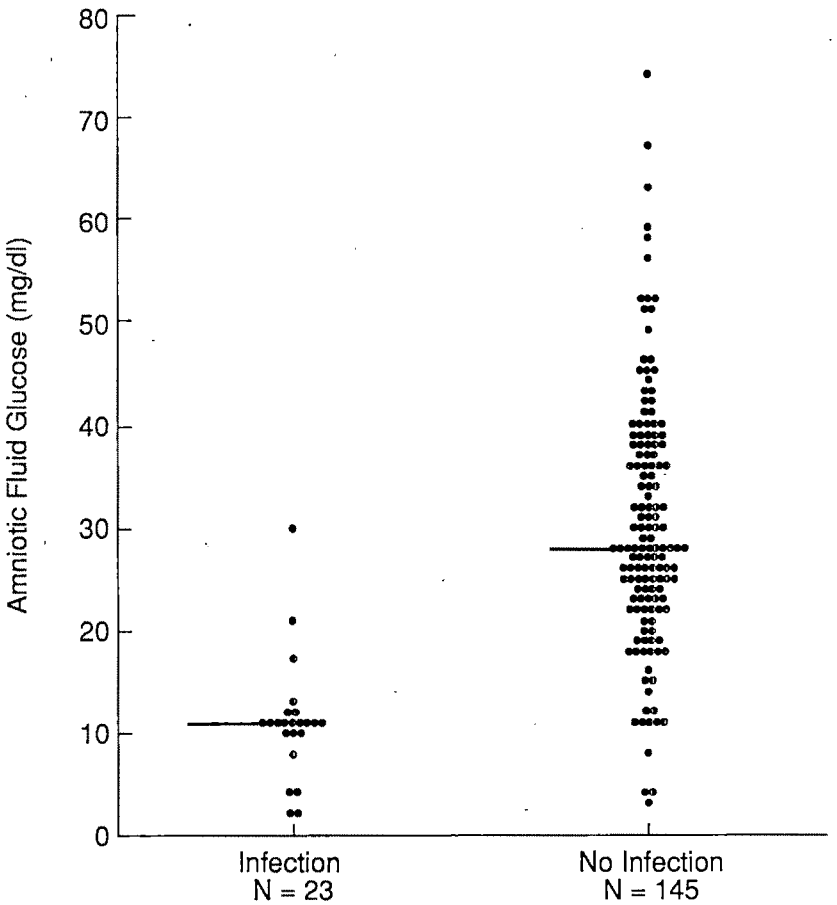

Fig. 1. Amniotic fluid glucose concentrations in the study population. The median amniotic fluid glucose concentration in patients with intraamniotic infection was significantly lower than in patients with negative amniotic fluid cultures (median 11 mg/dl, range 2 to 30 mg/dl vs median 28 mg/dl, range 3 to 74, respectively; $p < 0.0001$).

received parenteral tocolysis, 75% (9/12) went on to have a preterm delivery. Five of the nine patients with negative amniotic fluid cultures had been treated with antibiotics before undergoing amniocentesis, and one of the neonates subsequently had documented neonatal sepsis. In addition, one neonate was diagnosed to have congenital syphilis, but treponemas were not recovered from the amniotic fluid. Two of the three remaining patients had no clinical evidence of infection (maternal or neonatal), but their placentas showed acute inflammatory lesions (histopathologic chorioamnionitis).

Three patients with low glucose concentrations and negative amniotic fluid cultures were delivered at term. One patient had polyhydramnios of an unknown cause. The second patient had fever (101° F) and was treated with erythromycin because of a positive endocervical culture for *Chlamydia trachomatis*. The remaining patient had no evidence of an infectious process.

Table II displays the clinical course and microbiologic characteristics of patients with positive amniotic fluid cultures. Twenty-one percent (5/23) of patients had polymicrobial infections. Eight patients had negative Gram stains for microorganisms, and five of these had glucose concentrations below 14 mg/dl.

Clinical chorioamnionitis occurred in 2.4% (4/168) of patients. Three patients had positive amniotic fluid cultures for microorganisms and amniotic fluid glucose concentrations below 14 mg/dl, while the remaining patient had a negative culture of the amniotic fluid. This woman had lower abdominal pain, a temperature of 106° F, and leukocytosis (a white blood cell count of 22,300/mm^3) and underwent a cesarean section because of fetal distress. Placental examination did not show any evidence of inflammation, and the newborn had no evidence of sepsis. The amniotic fluid glucose concentration was 28 mg/dl.

The only neonate with sepsis was born to a woman with a positive amniotic fluid culture. The amniotic fluid glucose concentration in this case was 12 mg/dl.

Of the 168 patients included in the study, 149 received a trial of tocolysis (15 patients had a positive Gram stain, and four additional patients had tocolysis discontinued because of maternal or fetal indications). A low glucose concentration (<14 mg/dl) had a

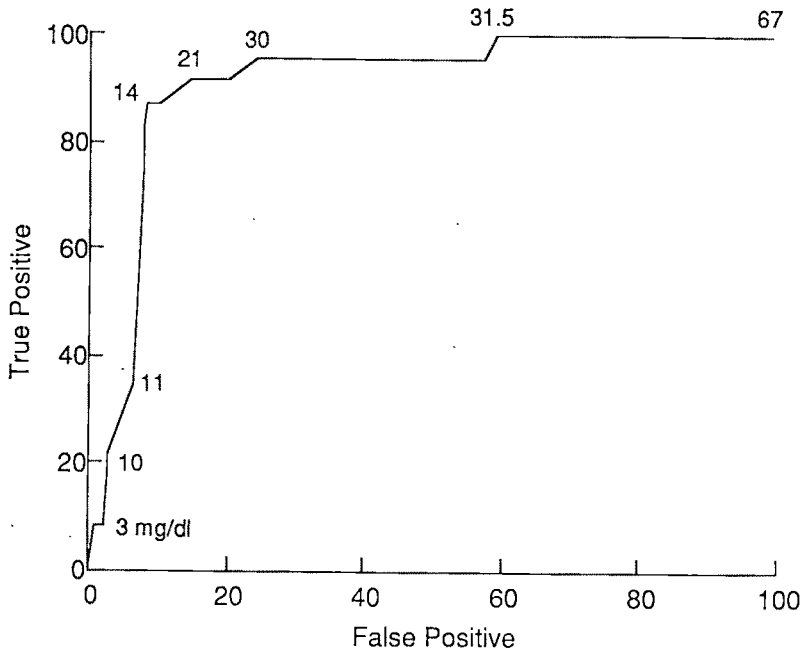

Fig. 2. A receiver operator characteristic curve analysis of the value of the amniotic fluid glucose concentration in diagnosis of a positive amniotic fluid culture (area under the curve 0.93, SE 0.03; z 14.1; $p < 0.001$). The numbers in the figure represent amniotic fluid glucose concentrations in milligrams per deciliter.

sensitivity of 37.9% (11/29), a specificity of 88.3% (106/120), a positive predictive value of 44% (11/25), and a negative predictive value of 85.4% (106/124) for the prediction of failure to respond to tocolytic therapy.

Comment

The data clearly demonstrate that microbial invasion of the amniotic cavity in women with preterm labor with intact membranes is associated with reduced glucose concentration in amniotic fluid (Fig. 1). Similar observations have been made in other body fluids (i.e., cerebrospinal fluid) in the setting of bacterial infection.[5-7]

Why is microbial invasion of the amniotic cavity associated with a reduced glucose concentration? In cerebrospinal fluid, three mechanisms have been invoked to explain a similar phenomenon: (1) metabolism of glucose by microorganisms, (2) consumption of glucose by activated neutrophils, and (3) changes in glucose transport across the hematoencephalic barrier. The most likely explanation for the low glucose concentration in cerebrospinal fluid is metabolism of glucose by white blood cells and bacteria. The evidence suggesting that glucose catabolism by activated neutrophils is the primary mechanism involved includes the following: (1) Neutrophils obtained from septic cerebrospinal fluid consume glucose at a rate that is two to three times higher than that of neutrophils from noninfected patients[10]; (2) incubation of cerebrospinal fluid with a combination of leukocytes and bacteria results in a lowered glucose concentration, while incubation by either one alone does not have the same effect[11]; (3) irradiated leukopenic dogs do not respond to pneumococcal meningitis with pleocytosis or with a reduction in cerebrospinal fluid glucose.[12] In contrast to bacterial infections, viral infections are not associated with a reduction in glucose concentrations. In viral infections the mononuclear cells are predominant. These cells are known to consume glucose at a lesser rate than neutrophils. An important question that remains to be answered is whether these aforementioned mechanisms are operative in amniotic fluid. The observation that six women who had negative amniotic fluid cultures for microorganisms and who also had acute inflammatory lesions of the placenta (see Table I) had reduced amniotic fluid glucose concentrations indicates that this finding could occur in the absence of viable microorganisms. Therefore, an inflammatory host response is probably associated with reduced glucose concentration in amniotic fluid.

In our study amniotic fluid glucose determinations, with a cutoff ≤14 mg/dl, had a sensitivity of 86.9% in the detection of intraamniotic infection while the sensitivity of the Gram stain was 65.2%. This difference fell short of reaching statistical significance with our sample size (23 patients with intraamniotic infections). The false-positive rate (100 − Specificity) of the Gram stain was lower than that of the amniotic fluid glucose concentration (0.7% vs 8.3%; $p < 0.05$). However, the

false-positive rate of amniotic fluid glucose concentration deserves comment. Seventy-five percent (9/12) of patients with low amniotic fluid glucose concentrations went on to deliver a preterm neonate despite intravenous tocolysis. Six of the seven placentas examined from women delivered prematurely had histologic evidence of chorioamnionitis. Thus an infectious process that was not detected by microbiologic examinations of

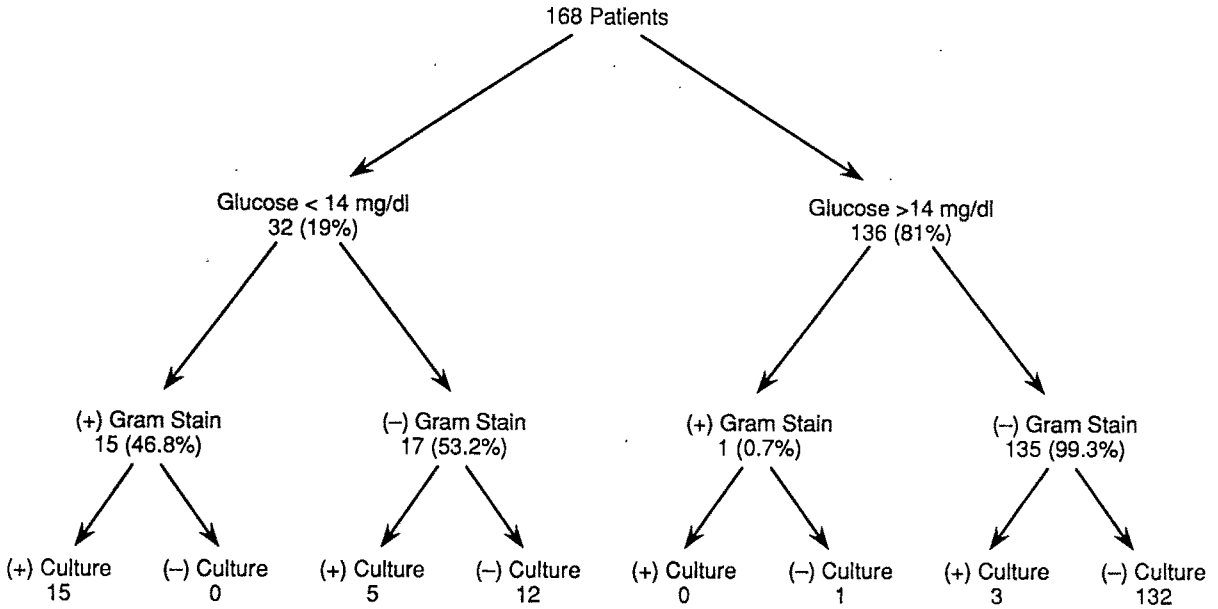

Fig. 3. Flow diagram of the results of amniotic fluid glucose determination, Gram stain, and culture of amniotic fluid.

amniotic fluid might have been responsible for the acute inflammatory lesions in the placenta.

The failure to recover microorganisms may have resulted from either antibiotic administration before amniocentesis (in five cases) or failure of growth of fastidious microorganisms. The possiblity exists that all nine patients with low amniotic fluid glucose concentrations and negative amniotic fluid cultures had an infectious process that escaped detection with current microbiologic techniques used in our laboratory.

There were three patients with low amniotic fluid glucose concentrations (8, 11, and 12 mg/dl, respectively) who were delivered at term. Two patients had clinical conditions that might explain the low concentration of glucose in amniotic fluid. The first patient had polyhydramnios, and this may have had a dilutional effect on amniotic fluid glucose concentration. The second patient had *Chlamydia trachomatis* endocervicitis and received antibiotics before amniocentesis. Antimicrobial therapy may have precluded successful isolation of a pathogen from amniotic fluid. We could not find any explanation for the reduced amniotic fluid glucose concentration observed in the third patient.

Despite the high sensitivity of amniotic fluid glucose determinations, a problem uncovered by this study is a false-positive rate of 8.3%. The seriousness of a false-positive result is dependent on the action taken after an abnormal test result. If the course of action is to perform a Gram stain of amniotic fluid, then a false-positive result is not clinically problematic. However, if the course of action is to deliver a preterm neonate believed to be infected, then there is the potential for serious consequences.

To examine the role of amniotic fluid glucose determinations in the rapid diagnosis of intraamniotic infection, we explored two diagnostic schemes: (1) simultaneous utilization with the Gram stain and (2) sequential use of both tests. Our data do not support the simultaneous use of both tests because the improvement in sensitivity is accompanied by a significant increase in the false-positive rate (from 0.7% to 9%).

The other alternative is to use the tests in sequence. The flow diagram provided in Fig. 3 displays the results of using a sequential diagnostic testing modality that incorporates amniotic fluid glucose determinations as a first-line test. A low glucose determination would have identified 15 of the 16 cases with positive Gram stains. Furthermore, a high glucose concentration has a high negative predictive value (97.8%).

Is there a role for this scheme of sequential testing in clinical practice? The Gram stain examination is the most widely used method for the rapid detection of bacteria in body fluids as it is rapid and inexpensive. However, Gram stain examination of amniotic fluid requires considerable experience. In a study conducted at our institution, considerable disagreement was found between results obtained by obstetric medical staff and trained laboratory personnel. Given the seriousness of the intervention implemented after identification of bacteria in a Gram stain, we concluded that Gram stain examinations of amniotic fluid should be read only by experienced laboratory personnel (Romero R, unpublished observations).

In most medical centers trained microbiology technicians are not available around-the-clock. Amniotic fluid glucose determination can assist the clinician in

deciding whether a Gram stain needs to be performed and analyzed immediately or whether it may be postponed until experienced personnel are available. In this context, amniotic fluid glucose determination has several advantages. The test is simple to perform and the required equipment is generally available in most obstetric units. Glucose determination is rapid, inexpensive, and does not require sophisticated interpretation by trained personnel.

The rapid diagnosis of infection in clinical medicine is a challenging problem. The approach used in other compartments, such as cerebrospinal fluid, consists of a combination of tests including the Gram stain, white blood cell and differential counts, and glucose and protein concentrations. A similar approach could be used for the detection of intraamniotic infection. Amniotic fluid glucose determinations may serve as an important component of this battery of tests. Further studies are required to explore the advantages and disadvantages of this approach. Other issues that need to be addressed are the effects of changes of amniotic fluid volume and maternal glucose intolerance on the clinical value of this test.

We gratefully acknowledge the assistance of Carol A. Brekus, MSN, CNM, and Valerie W. Kraemer, MFA.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

False-negative syphilis screening: The prozone phenomenon, nonimmune hydrops, and diagnosis of syphilis during pregnancy

Kathleen Berkowitz, MD, Laxmi Baxi, MD, and Harold E. Fox, MD
New York, New York

The prevalence of congenital syphilis is rapidly rising in several areas of the United States. Efforts to control the disease depend on the effectiveness of established screening strategies and treatment of infected pregnant women. False-negative test results hinder these efforts and leave the fetus at risk for acquiring congenital syphilis. Recently we encountered four cases of false-negative syphilis serologic results in women who gave birth to infants with congenital syphilis. The false-negative results were caused by the prozone phenomenon. The prozone phenomenon, seen during primary and secondary syphilis, occurs because a higher than optimal amount of antibody in the tested sera prevents the flocculation reaction typifying a positive result in reagin tests. Serum dilution is necessary to make the correct diagnosis. We recommend that for any pregnant woman with apparently negative syphilis serologic results in whom fetal compromise of unknown etiology exists, particularly nonimmune hydrops, nontreponemal testing should be repeated using serum dilutions to prevent a missed diagnosis of syphilis. We further recommend serum dilution as a routine procedure for all pregnant women in areas of high syphilis prevalence. (Am J Obstet Gynecol 1990;163:975-7.)

Key words: Prozone phenomenon, false-negative syphilis screening, serum dilution, screening strategies, nonimmune hydrops

A dramatic increase in the prevalence of syphilis has been noted in several areas of the United States during the past 2 years. The prevalence of congenital syphilis has also risen rapidly and in some areas is now considered epidemic.[1] Attempts to control this epidemic hinge on adequate surveillance, identification, and treatment of infected women.

The use of nontreponemal serologic tests is widely accepted as an effective screening strategy for the detection of syphilis during pregnancy. However, in some clinical situations difficulty in diagnosis results in misidentification of the true disease state despite the use of highly accurate tests. False-positive results have been reported in many conditions including pregnancy.[2-5] Serial testing, dark-field examination, or treponemal tests clarify the diagnosis in these situations. False-negative results may occur when the patient is tested long after treatment, during late-latent syphilis, or as a result of the prozone phenomenon. A false-negative error presents a serious problem because an infected woman would then fail to receive treatment, leaving her fetus vulnerable to the disastrous consequences of congenital syphilis.

The prozone phenomenon occurs when an excess of antibody in the sera being tested prevents the formation of the antibody-antigen lattice network needed to visualize a positive flocculation reaction.[6] Antibody may remain undetected if the antigen is too dilute or too concentrated. The zone of concentrations in which precipitation or flocculation can occur is called the "optimal zone." When a sample shows a negative reaction because of antibody-antigen concentrations outside the optimal zone, a "zonal reaction" or prozone phenomenon has occurred.[7] The term "sero-negative syphilis" was coined in 1950 to describe the effect.[8] The prozone phenomenon can affect any agglutination reaction and its first description in 1907[9] predates even the Wassermann complement fixation test. The prozone phenomenon can cause a false-negative result when Venereal Disease Research Laboratories or rapid plasma reagin tests are used and occurs in approximately 2% of cases of primary or secondary syphilis.[10] Serum dilution reestablishes the proper concentrations of antibody and antigen that allow lattice formation.

Four women with false-negative syphilis serologic results (Becton-Dickinson rapid plasma reagin card test, Rutherford, N.J.) gave birth to infants with congenital

syphilis at the Sloane Hospital for Women in 1989. The false-negative results were caused by the prozone phenomenon. This article details their clinical presentations and the management difficulties encountered as a result of the prozone phenomenon.

Case reports

Case 1. A 26-year-old woman (gravida 8, para 3-0-4-2) was seen at 32 weeks' gestation with a complaint of decreased fetal movement. Rapid plasma reagin testing at 16 weeks of gestation and in previous years had been reported as negative. There was no maternal clinical evidence of syphilis. TORCH titers and a rapid plasma reagin test result were reported as negative on admission. Ultrasonography revealed bilateral hydrocele, polyhydramnios, and possible hydrops. During cordocentesis for karyotyping and acid-base determination, bradycardia and prolonged umbilical cord bleeding occurred that necessitated emergency cesarean section. A live-born male infant weighing 2525 gm with Apgar scores of 0 and 3 at 1 and 5 minutes was delivered. The infant had significant metabolic acidosis, thrombocytopenia, and physical signs of congenital syphilis. There was no cord hematoma. A second maternal serologic sample (Becton-Dickinson rapid plasma reagin card test) yielded an initial negative result and a positive titer of 1:64 on serum dilution; the treponemal test result was positive.

Case 2. A 21-year-old woman (gravida 3, para 1-0-1-1) at 32 weeks' gestation who had received no prenatal care was seen with malaise and decreased fetal movement. There was no clinical evidence of syphilis and she reported past negative serologic results. Fetal heart rate monitoring revealed a minimally reactive tracing. Amniotic fluid was increased and the placenta appeared edematous on ultrasonogram. Rapid plasma reagin and TORCH titers were reported as negative on admission. The original serum sample was diluted to evaluate a possible prozone phenomenon because of strong clinical suspicion of intrauterine infection. A cesarean section was performed for management of fetal distress. A male infant weighing 1460 gm with Apgar socres of 5 and 8 at 1 and 5 minutes was delivered. The infant had clinical and serologic evidence of congenital syphilis. Long-term follow-up of this infant is not available. Serum dilution titer was 1:256 with positive treponemal testing.

Case 3. A 36-year-old woman (gravida 6, para 4-0-1-0) was seen at term in active labor. She had no clinical or historical evidence of syphilis infection. A perineal lesion seen 1 week earlier was positive after culture for herpes simplex virus and a rapid plasma reagin test on admission was reported as negative. Fetal distress was seen on admission and a cesarean section delivery produced a male infant with Apgar scores of 1 and 1 at 1 and 5 minutes. The infant had petechiae, hepatosplenomegaly, thrombocytopenia, and died 7 hours post partum. Pathologic studies showed a pale and bulky placenta. Serum dilution yielded a postive titer of 1:128 with positive treponemal testing.

Case 4. A 30-year old woman (gravida 4, para 1-0-2-1) at 27 weeks' gestation had contractions and decreased fetal movement. She had received no antenatal care and had a history of adequately treated primary syphilis in 1986. The rapid plasma reagin test for syphilis on admission was negative despite physical findings including condyloma lata. Ultrasonography confirmed a 27-week intrauterine death with hydrops and placentomegaly. The patient was spontaneously delivered of a severely macerated, hydropic fetus weighing 2070 gm. Petechia, splenomegaly, and funisitis[11] were noted at autopsy and the placenta was bulky and pale. Serum dilution yielded a rapid plasma reagin titer of 1:256 with positive treponemal testing.

Comment

The laboratory diagnosis of syphilis can be made with darkfield microscopy or serologic testing. The mobile, corkscrew-shaped organisms of *Treponema pallidum* can be identified microscopically by examination of fresh exudate with a dark-field condenser. Serologic tests are divided into treponemal and nontreponemal tests. Treponemal tests detect antibodies against *T. pallidum* by incubation of the specimen with labeled anti–*T. pallidum* globulin (fluorescent treponemal antibody-absorption test) or sensitized sheep erythrocytes (microhemagglutinin test). The first treponemal test developed in 1949 was the *T. pallidum* immobilization test. It has been largely replaced by the more sensitive, less expensive tests mentioned earlier. The nontreponemal tests, such as the VDRL or rapid plasma reagin card test, use purified cardiolipin-lecithin-cholesterol antigen. The VDRL test requires heated serum and a positive result is determined microscopically by visualizing flocculation. The rapid plasma reagin card test and the automated reagin test use unheated serum and stabilized cardiolipin antigen suspended in charcoal. The results are read macroscopically as a result of agglutination. This approach has the advantage of being simpler to perform and standardize. When evaluating the efficacy of treatment by measurement of serum titers, the same nontreponemal test should always be used because there may be a marked variation in titers between tests. The nontreponemal tests generally are more sensitive in the diagnosis of primary syphilis, but in secondary syphilis there is no difference in sensitivity between nontreponemal and treponemal tests.[12] Treponemal tests are more sensitive in the diagnosis of tertiary syphilis.

The prozone phenomenon occurs when the amount of antibody in a particualr serum sample is too high to allow formation of the antibody-antigen complex necessary to visualize flocculation or agglutination. Syphilitic infection may be hidden in those patients whose serologic results are rendered negative by the prozone phenomenon. This is a particulary worrisome problem in asymptomatic pregnant women. Because the true

cause of fetal compromise is masked, the management of pregnancy and labor cound potentially be misguided. Diagnosis of congenital syphilis with its attendant risk of thrombocytopenia and anemia affect management of the timing and route of delivery. The last case illustrates that routine serologic study may be misleading in the diagnosis of inadequately treated or reacquired disease.

The predictive value and cost benefit of screening pregnant women for syphilis depends on the prevalence of the disease in the population being tested. Because the cost of treating infants with congenital syphilis is so high, screening and treatment of almost all populations of infected women is cost beneficial.[13] The prevalence of syphilis in the population of women who were delivered at the Sloane Hospital for Women in 1988 was 2.7% (140 cases in 5280 deliveries). Of the infants born to these women, at least seven (1.3 per 1000 deliveries) had symptomatic congenital syphilis. Approximately two thirds were asymptomatic but had serologic test results compatible with the diagnosis of congenital syphilis and required intravenous antibiotic therapy.

We recommend that serum dilution be performed to evaluate the possibility of a false-negative result caused by the prozone phenomenon for any woman with negative serologic results in whom intrauterine infection is suspected. Serum dilution should also be included in the workup of nonimmune hydrops. When clinically indicated, ultrasonography is helpful in discovering evidence of intrauterine infection such as placentomegaly, polyhydramnios, or intrauterine growth retardation. We further recommend that in populations with a high prevalence of syphilis every woman should have rapid plasma reagin testing with serum dilution on presentation for antepartum care and again in the third trimester.

Intrapartum hepatitis B screening in a low-risk population

J. M. Ernest, MD,[a] Laurence B. Givner, MD,[b] and Robert Pool, MD[c]
Winston-Salem, North Carolina

Intrapartum hepatitis B surface antigen testing was performed on all laboring patients admitted to Forsyth Memorial Hospital in Winston-Salem, North Carolina from December, 1988 through November, 1989. Of the 5580 patients tested, eight patients had test results positive for hepatitis B surface antigen (overall prevalence rate of 0.14%). HBsAg was present in 0.3% of public patients and 0.08% of private patients. Of the seven patients who were not known to be positive for hepatitis B surface antigen before pregnancy, three had identifiable risk factors for hepatitis B virus. The time interval from birth to administration of hepatitis B immune globulin in the newborn averaged 13.3 hours. Patient cost per new case detected was $13,203. Intrapartum hepatitis B surface antigen screening with an assay performed once daily allows for timely administration of hepatitis B immune globulin to the newborn in accordance with recommendations of the American College of Obstetricians and Gynecologists, although some newborns receive hepatitis B immune globulin after the 12-hour birth-to-administration interval recommended by the Centers for Disease Control. (AM J OBSTET GYNECOL 1990;163:978-80.)

Key words: Hepatitis B virus, intrapartum screening, hepatitis B surface antigen

Vertical transmission of hepatitis B virus represents one of the most efficient modes of hepatitis B virus infection. In the United States an esimated 16,500 women who are positive for hepatitis B surface antigen (HBsAg) give birth yearly and approximately 3500 of their infants become chronic hepatitis B virus carriers.[1] Treatment of these newborns soon after birth with hepatitis B immune globulin and subsequently hepatitis B virus vaccine would prevent 85% to 90% of exposed infants from becoming chronic carriers.[2]

In June 1988 the Advisory Committee on Immunization Practices of the Centers for Disease Control recommended universal screening of all pregnant women early in the prenatal period[1] because studies from large inner-city hospitals found that only 35% to 65% of HBsAg-positive patients were identified by limiting screening to women considered high-risk by Advisory Committee on Immunization Practices guidelines.[3-5] These universal screening recommendations are based in part on prevalence rates in large inner-city hospitals. Although universal screening has been estimated to be cost effective in areas where the prevalence of hepatitis B virus infection is at least 0.06%,[6] many practitioners in hospitals outside inner-city areas remain reluctant to add the additional costs of routine hepatitis B virus screening to prenatal care. Practitioners are also concerned that maternal hepatitis B virus test results performed early in gestation are not available to the pediatrician early in the newborn period and are concerned about untested patients who are transferred at the onset of labor and patients who receive no prenatal care.

Because of these concerns we examined the feasibility and cost of universal hepatitis B virus screening at the time of labor in a non-inner-city population in western North Carolina by addressing three questions. (1) What is the prevalence of HBsAg-positive women in this population? (2) Will screening for HBsAg at the time of labor allow for timely immunization of the newborn? (3) What is the cost per case detected in this population?

Methods and material

Since December 1988 all patients in labor who came to Forsyth Memorial Hospital in Winston-Salem, North Carolina, have been screened for HBsAg. Approximately 5000 births per year occur at Forsyth Memorial Hospital to Forsyth county residents (which includes 94% of the total births from Forsyth County) and an additional 300 to 400 births per year occur at Forsyth Memorial Hospital to women transferred from the 19-county referral area surrounding Forsyth county. Patients are transferred to Forsyth Memorial Hospital to receive high-risk obstetric care from the Obstetrics Department of Bowman Gray School of Medicine of Wake Forest University. Winston-Salem has a population of 150,000. The largest city from which referrals are received, Greensboro, North Carolina, has a population of 200,000. Approximately 70% of the obstetric patients who are delivered at Forsyth Memorial Hospital are white, and 70% of the overall pa-

Table I. Patients with positive HBsAg and neonatal hepatitis B immune globulin administration

Patient No.	*Type of prenatal care*	*Maternal risk factor*	*Known positivity before admission*	*Intervals (hr)*		
				Admission–result known	*Admission-birth*	*Birth–hepatitis B immune globulin given*
1	Private	Filipino	No	22.5	31.0	4.0
2	Public	None	No	19.0	4.0	18.0
3	Public	Intravenous drugs	No	17.0	137.0	0.5
4	Private	None	No	29.5	12.5	23.0
5	Public	None	No	17.0	6.0	13.0
6	Private	Korean	Yes	—	30.5	1.0
7	Public	Multiple sexually transmitted diseases	Yes	—	4.0	7.0
8	Public	None	No	32.0	14.0	21.0

tient population receive their care from private physicians. Eighty percent of patients who receive care from a private physician are white, and the majority of the remainder are black. The prevalence of illicit drug use and sexually transmitted diseases in the private group is unknown.

Except for selected situations, all Medicaid patients are seen and followed through local health departments by resident physicians from Bowman Gray School of Medicine. Therefore all patients seen by private physicians have private third-party coverage or are able to self-pay the physician's fee and hospital costs of delivery. Of the 30% of patients who receive their care through local health departments, approximately 55% are white, and the remainder black, with an occasional patient of Hispanic, Oriental, or Native American background as in the private population. The admitted use of illicit parenteral drugs is increasing in our public health department patients and currently appears to be in the 5% to 15% range. The prevalence of *Neisseria gonorrhoeae* infection at the first prenatal visit is 2% to 3%, and *Chlamydia trachomatis* 5% to 6%.

Patients were screened for HBsAg with the AUSRIA 11-125 radioimmunoassay (Abbott Laboratories, North Chicago). The assay was performed once daily and positive results (defined as counts ≥2.1 times the mean of the negative controls) were confirmed with standard hepatitis B profiles including hepatitis B e antigen (HBeAg), and antibodies to hepatitis B core, surface, and e antigens. Patients with a positive test for HBsAg were referred for infectious disease consultation and their infants received hepatitis B immune globulin (and hepatitis B virus vaccine) as soon after birth as test results were available.

Results

During the 12 months from Dec. 1, 1988, through Nov. 30, 1989, 5580 laboring patients were screened for HBsAg. Eight patients were found to be HbsAg-positive (prevalence of 0.14%). The rate in public patients was 0.3% and in private patients was 0.08%.

One of the eight patients was Korean and a known chronic hepatitis B virus carrier and one had been found to be HBsAg–positive at a previous admission for preterm labor (patients 6 and 7, respectively, Table I). The remaining six were not known to be positive for HBsAg before labor. Four of the six (67%) had no known risk factors for hepatitis B virus infection as defined by the Advisory Committee on Immunization Practices.[3] Three of these four previously unknown HBsAg-positive patients were public health department patients and one was a private patient.

In the six patients not known to be positive for HBsAg at the time of admission, the average time from admission in labor until HBsAg results were known was 23 hours (range, 17-32 hours) (Table I). The time interval from birth to administration of hepatitis B immune globulin averaged 13.3 hours (range, 0.5 to 23.0 hours).

The actual hospital cost of each HBsAg assay was $12.90, for a total cost of $71,982 for the 12 months studied. Actual cost per new case detected (excluding the one patient previously known to be a chronic carrier) was $10,283. The cost to the patient of the HBsAg test used for screening was $15 per patient for the first 6 months, and $18 for the last 6 months, for a total cost of $94,421 for the 12-month period. The cost per new case detected (excluding the one patient previously known to be a chronic carrier) was $13,488 per case.

Comment

Infants born to women positive for HBsAg (and hepatitis B e antigen) have a 90% risk of hepatitis B virus infection. Ninety percent of infected infants become chronic carriers at risk for the development of cirrhosis and hepatocellular carcinoma.[1] The development of the carrier state can be prevented in 85% to 90% of infants born to HBsAg-positive mothers by prompt administration of hepatitis B immune globulin after birth

and a series of hepatitis B virus vaccine injections.[2] Whereas infants are at highest risk for hepatitis B virus infection when the mother is both HBsAg- and HBeAg-positive,[7] fatal cases of hepatitis B virus infection have been reported in infants of HBsAg-positive, HBeAg-negative mothers,[8] and infants born to HBsAg-positive women should receive immunization regardless of maternal HBeAg status.

Current Centers for Disease Control recommendations include universal screening of all pregnant women for hepatitis B virus infection early in gestation as well as availability of HBsAg results within 24 hours for women admitted in labor who have not had prenatal screening.[1] Prompt treatment of the infant after birth then can occur. In large inner-city populations with high prevalence rates of hepatitis B virus, these recommendations are generally considered appropriate. In other areas where the prevalence of hepatitis B virus is lower, the cost effectiveness of universal screening may be questioned because of the presumed low likelihood of positive results. Logistically, transmitting HBsAg information from the maternal physician's office to the pediatrician at the time of birth may impede timely hepatitis B immune globulin administration to the infant, and centers that receive transfer patients or patients without prenatal care may have substantial numbers of patients in labor who have not been screened early in gestation. An occasional HBsAg-negative patient in early pregnancy may acquire hepatitis B virus during pregnancy with minimal symptoms.

On the basis of the 5580 patients in this study, intrapartum HBsAg testing of all patients with an assay performed once daily, while obviating the need for screening in early pregnancy, will not allow reporting of every patient's HBsAg status within 24 hours of admission nor will it allow for administration of hepatitis B immune globulin to exposed infants within 12 hours of birth as recommended by the Centers for Disease Control.[1] Two of the six infants born to women not known to be HBsAg-positive at the onset of labor received hepatitis B immune globulin within 12 hours of birth and four received hepatitis B immune globulin more than 12 hours (13, 18, 21, and 23 hours, respectively) after birth (Table I). The apparent decline in efficacy of hepatitis B immune globulin as the interval from birth to administration increases was the basis for the Centers for Disease Control recommendation of administration of hepatitis B immune globulin within 12 hours of birth.

The population base and regional characteristics of our patients would suggest a low-risk group for hepatitis B virus infection, and the 0.14% prevalence is slightly lower than the national average of 0.2%.[6] When the prevalence is at least 0.06%, direct and indirect costs of universal antepartum screening as well as immunization of the newborn allow for a cost-effective prevention program.[6] Shifting the time of screening to the intrapartum period allows for continued cost effectiveness while obviating the logistic problems described above.

Universal intrapartum HBsAg screening in this low-risk population identified seven previously undetected HBsAg-positive women (four without any identifiable risk factors for hepatitis B virus). This approach permitted timely immunization of their infants with hepatitis B immune globulin (and subsequently hepatitis B virus vaccine). However, once-daily performance of the HBsAg assay did not permit strict adherence to the Centers for Disease Control recommendations to obtain all HBsAg test results within 24 hours of admission or administration of hepatitis B immune globulin to the infant within 12 hours of birth.

These findings must be considered in planning of policies for screening pregnant women for hepatitis B virus infection. Hospitals without daily HBsAg testing capabilities should continue to consider prenatal testing of their obstetric patients.

Risk factors associated with the increasing prevalence of pneumonia during pregnancy

K. Berkowitz, MD, and A. LaSala, MD
New York, New York

A retrospective chart review of 1120 antepartum admissions revealed the prevalence of antepartum pneumonia rose to 1 per 367 deliveries. A total of 26 cases in 9560 deliveries were identified with criteria of fever >39° C, productive cough, and radiologic findings of infiltrates or consolidation. Pregnancy-related outcome variables studied were prevalence of preterm labor or birth, birth weight, and trimester of occurrence. Pneumonia characteristics studied were rate and type of organisms recovered, seasonality, and severity of the illness and radiologic findings. Exposure variables relating to the development of pneumonia studied were underlying medical conditions, hematocrit, human immunodeficiency virus status, and drug use. Birth weight, hematocrit, human immunodeficiency virus status, and drug use were compared with a randomly selected sample of women drawn from the general population delivered of infants during the study time period. One patient experienced preterm delivery, which occurred 1 month after cure of pneumonia. Birth weight was significantly lower in the study group (2770 ± 224 gm versus 3173 ± 99 gm, $p < 0.01$). The most common organism recovered was *Streptococcus pneumoniae*. A total of 42% of patients had multilobar involvement and two required intubation. Cocaine use (52% in the study group versus 10% in the general population, $p < 0.01$) and human immunodeficiency virus positivity (24% in the study group versus 2% in the general population, $p < 0.01$) were significant risk factors for antepartum pneumonia. (Am J Obstet Gynecol 1990;163:981-5.)

Key words: Pneumonia, human immunodeficiency virus status, drug use, pregnancy outcome

The morbid complications of antepartum pneumonia have markedly changed since the introduction of antibiotic therapy. In the preantibiotic era preterm labor and maternal mortality were frequent sequelae of pneumonia.[1, 2] Since the use of antibiotics began, maternal mortality has significantly decreased.[3, 4] The effect of antibiotic therapy on the prevalence of preterm labor has variably been reported as decreased[3] or unchanged.[5] The prevalence of antepartum pneumonia has fallen from a rate in the preantibiotic era (before 1956) of 1 per 118 deliveries[2] to 1 per 2288 deliveries.[3] The most recent case review reported a slightly increased rate of 1 per 1287 deliveries.[5]

In the past 5 years drug use and human immunodeficiency virus (HIV) infection have dramatically increased in certain populations of pregnant women. Previous large studies have not examined the effect of these problems on the epidemiologic factors, pathophysiology, and morbidity of pneumonia in pregnancy. This study was designed to discover whether recent changes have occurred in the cause, morbidity, or sequelae of antepartum pneumonia as a result of HIV status or drug use. We reviewed all cases of community-acquired pneumonia diagnosed during pregnancy at the Sloane Hospital for Women in 1988 and 1989 to determine the pathogenesis and risk factors involved in the development of this disease.

Material and methods

Discharge diagnostic chart coding was reviewed for 1120 antepartum admissions to the Sloane Hospital for Women from January 1988 to November 1989. The Sloane Hospital for Women is a tertiary care university hospital in New York City, serving a large indigent population and delivering more than 5000 infants per year. A total of 213 charts in which the diagnosis was related to respiratory complaints, "fever," or was unclear underwent extensive chart review. With inclusion criteria of productive cough, radiologic findings of infiltrates, and fever >39° C, 26 cases of pneumonia were identified in 25 patients. Alternative sources of information including review of residency experience logs did not yield any cases of pneumonia.

Exposure variables, outcome variables, and characteristics of the pneumonia were examined. Pregnancy-related outcome variables were birth weight, trimester of occurrence, and prevalence of premature labor or delivery. Pneumonia characteristics studied were rate

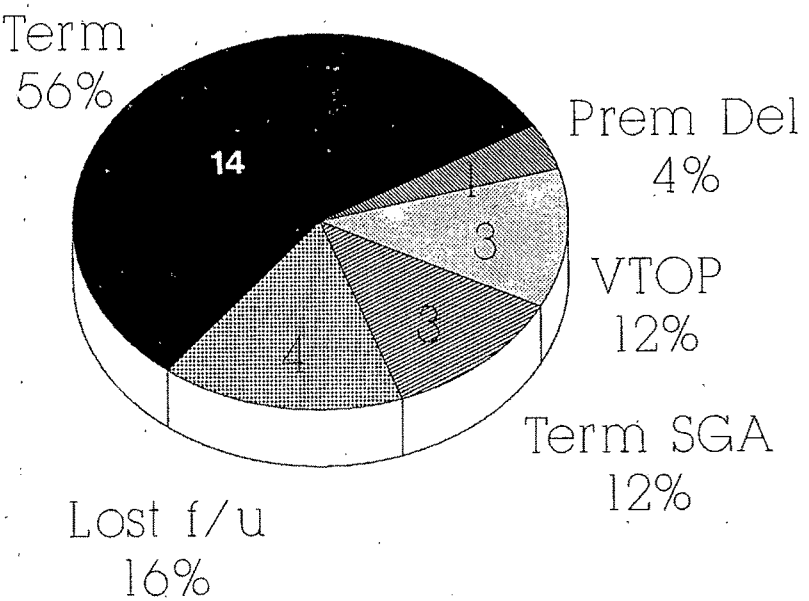

Fig. 1. Pregnancy outcome in 25 patients with pneumonia. *Prem Del,* premature delivery; *VTOP,* voluntary abortion; *f/u,* follow-up.

of recovery, type of organisms cultured, radiographic findings, seasonality, and severity of the illness. Exposure variables thought to affect susceptibility to pneumonia—underlying medical conditions, hematocrit, drug use as determined by urine toxicology screens, and HIV status—were examined.

Comparison groups were randomly selected from women cared for and delivered of infants at the Sloane Hospital for Women during the study period. The birth weight comparison group was selected by recording the second entry on each of 100 successive pages of the delivery room log. Hematocrit comparisons were obtained from the first prenatal visit data of randomly selected women first seen at the Sloane High-Risk Clinics for antepartum care. There was no significant difference in the percentage of values obtained during the second or third trimester between the groups. The comparison groups for HIV status and frequency of drug use were derived from independent studies conducted in the same population during the same time period covered by this study. Urine toxicology data were obtained from all women first seen in active labor (Unpublished data). Anonymous serosurveys conducted at the Sloane Hospital for Women in 1989 of women who required venipuncture in the delivery room were used to determine the HIV positivity rate in the general population. Statistical comparisons were made with the two-tailed paired Student t test, χ^2, and the Fischer exact test where appropriate.

Results

Pregnancy-related outcome variables. No cases of premature labor or delivery occurred during the hospitalization for pneumonia. Seventeen pregnancies reached term without premature labor, including two sets of twins. One patient had premature labor with unsuccessful tocolysis approximately 1 month after adequate treatment and resolution of the pneumonia. Four were lost to follow-up and three were voluntarily terminated (Fig. 1). Birth weight was significantly less in patients with antepartum pneumonia than that in the comparison group (2770 ± 224 gm versus 3173 ± 99 gm, $p < 0.01$, see Fig. 2). Few cases of pneumonia were diagnosed in the first trimester (Fig. 2).

Pneumonia characteristics. Fifteen cases occurred from September to January. There were no cases during the summer months of July or August (Fig. 3). Many patients (42%) had multilobar involvement with the lower lobes being most frequently involved (Fig. 4). Sputum cultures were positive in 27% of patients and blood cultures were positive in 15%. Viral cultures were not obtained. The most common organism identified in sputum cultures were *Streptococcus pneumoniae* (six cases) and it was the only organism recovered in blood cultures. Other pathogenic organisms recovered included *Haemophilus influenzae, Legionella pneumophila, Mycobacterium avium* complex, and *Mycoplasma* (Table I). In one patient who had community-acquired antepartum pneumonia, *Pneumocystis carinii* was recovered 1 month post partum. The episode was not included for analysis in this study because it occurred post partum. Eighteen patients required supplemental oxygen. Complications of bronchospasm that required intubation developed in two patients with a history of asthma. In each case the patient was extubated within 24 hours. Empiric antibiotic therapy with cefoxitin or cefuroxime

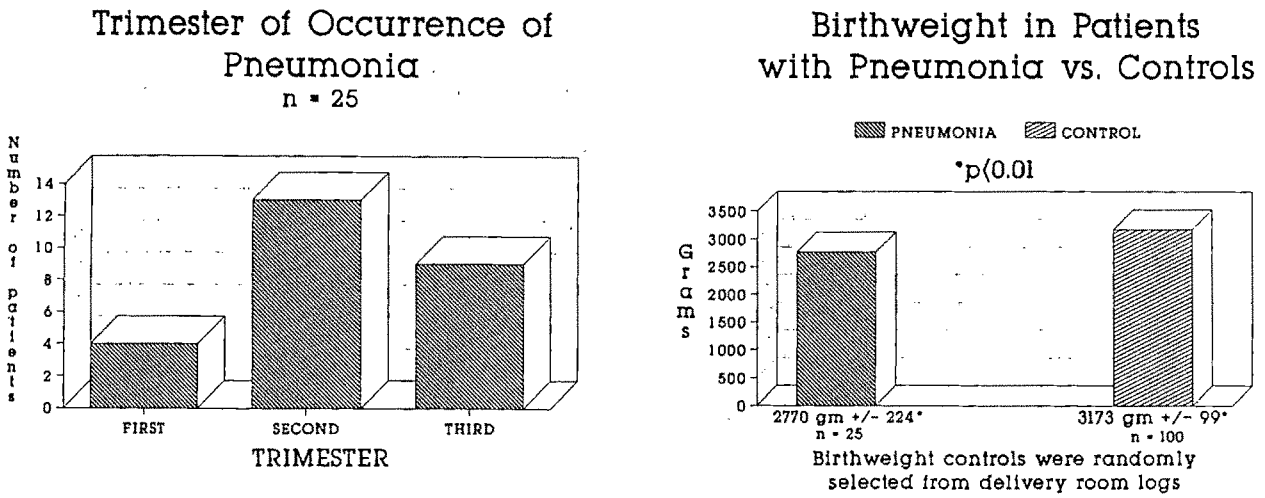

Fig. 2. Trimester of occurrence and infant birth weight in patients with pneumonia.

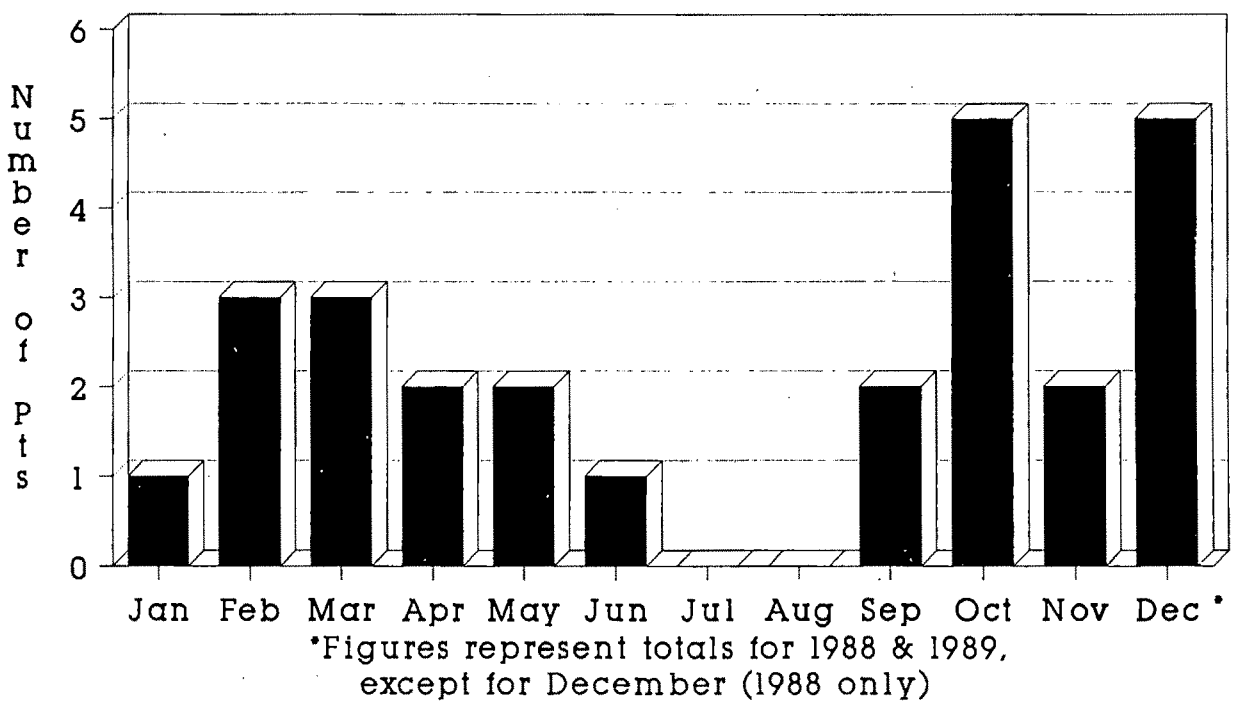

Fig. 3. Seasonal incidence of antepartum pneumonia.

and erythromycin was begun in all patients. When cultures were positive, therapy was changed to the most appropriate antibiotic. Three patients received trimethoprim-sulfa. Most patients were observed to defervesce by the third day of therapy. The average length of hospitalization was 8.4 days.

Exposure variables. Ten patients had underlying medical conditions including iron deficiency anemia, history of asthma or tuberculosis, or previous episode of pneumonia. Hematocrit was significantly lower in study patients than in the comparison group (31.5% ± 0.95% versus 34.9% ± 0.90%, $p < 0.01$, see Table II). Drug use was determined by urine toxicology screening and when positive was documented as cocaine without exception. The study group had a significantly higher percentage of positive urine toxicology screening results (52% versus 10%, $p < 0.01$, see Fig. 5). Patients who used cocaine reported that their preferred method of drug ingestion was smoking either cocaine or "crack" cocaine. HIV status was determined in 11 cases and three were positive. Three had other evidence of HIV positivity such as altered T-cell ratios

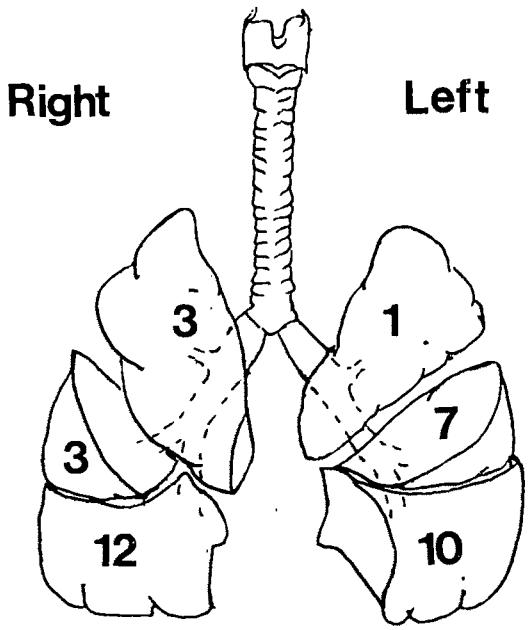

Fig. 4. Radiologic findings of lobar involvement. A total of 42% of patients (n = 25) had multilobar involvement, with the lower lobes most often affected.

Table I. Pathogens recovered in antepartum pneumonia

Organisms identified		*Positive cultures*	
Streptococcus pneumoniae	6	Sputum	27%
Haemophilus influenzae	2	—	—
Legionella	1	Blood	15%
Mycoplasma	1	—	—
Mycobacterium avium complex	1	—	—

S. pneumoniae was the only organism identified in blood cultures. *Pneumocystis carinii* was recovered from one patient postpartum.

or opportunistic infection concurrent with pneumonia. HIV positivity and T-cell function abnormalities were significantly higher in the study group than in the comparison group (24% versus 2%, $p < 0.01$, see Fig. 5).

Comment

The prevalence of antepartum pneumonia has steadily declined from 1939 to 1982 with the advent of antibiotic therapy. This study documents a sevenfold higher prevalence of pneumonia as compared with the recently published rate of 1 per 2288 deliveries.[3] This increase is observed against the background of a changing obstetric population. Greater numbers of women with chronic respiratory disease, an immunocompromised state, or drug addiction are achieving pregnancy. Several patients in this study were severely ill and required prolonged intravenous antibiotic therapy to adequately treat sepsis and multilobar involvement. Two required ventilatory support. Such hospitalizations place a great strain on already overused critical care resources and funds.

Table II. Medical conditions associated with pneumonia

	No. of patients	%
Medical condition		
Asthma	6	—
History of pneumonia	4	—
History of tuberculosis	2	—
Iron deficiency anemia	3	—
Average hematocrit		
Study (n = 25)*	—	31.5 ± 0.95
Control (n = 100)*	—	34.9 ± 0.90

Controls were randomly obtained from patients receiving care in the Antepartum High Risk Clinic.
*p <0.01.

The finding of significant anemia is in agreement with the findings of Benedetti[3] and reflects the general poor health and nutritional status of the patients in this study. Multiple underlying medical conditions, anemia, and HIV positivity were common. There were no maternal deaths recorded despite the abundance of poor prognostic factors already mentioned. Early aggressive use of antibiotics and advanced respiratory support therapies certainly contributed to the absence of maternal mortality.

There were no episodes of preterm labor during acute hospitalization for pneumonia. Two sets of twins reached term. There was one preterm delivery that was unrelated to the episode of pneumonia. The scarcity of preterm labor in this study was not expected given the severity of illness, but might be a result of early treatment of the disease. Whereas infants were significantly smaller than those in the general population, only three met small-for-gestational-age criteria. A multivariate analysis would have helped to elucidate the exact causes of decreased birth weight but the small number of subjects in this study precluded such analysis. There were no neonatal deaths. Analysis of neonatal length of hospital stay was not performed because many of these infants were housed in the hospital awaiting placement by the Bureau of Child Welfare. Long-term follow-up is not available at this time.

The etiologic agents traditionally associated with community-acquired pneumonia were also those most commonly recovered in this study. The only documented *Pneumocystis carinii* infection occurred in a patient who had previously had *Streptococcus pneumoniae*. HIV positivity and cocaine inhalation were highly significant risk factors and the mechanisms by which they increase host susceptibility have not been completely investigated.

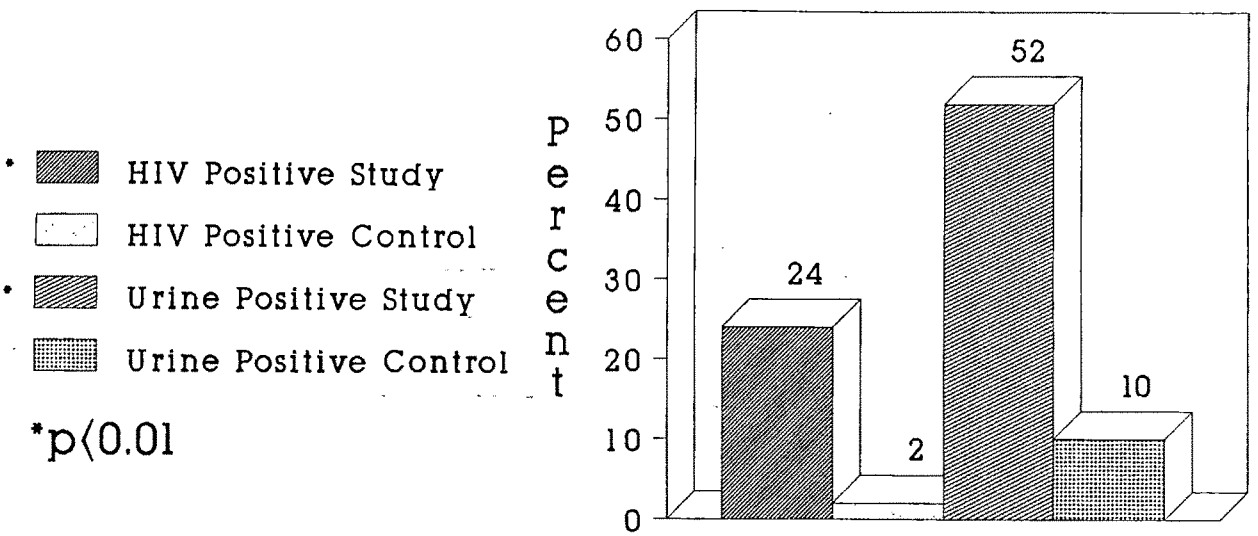

Fig. 5. HIV status and drug use in patients with pneumonia versus controls.

Cocaine inhalation can cause acute pulmonary edema and increased susceptibility to ordinary pneumonia,[6] probably through increased pulmonary capillary permeability. The "crack lung" syndrome is characterized by transient pulmonary infiltrates, fever, eosinophilia, and elevated immunoglobulin E levels.[7] Decreased diffusion across the alveolar membrane has been reported.[8] Another mechanism by which cocaine inhalation may increase host susceptibility is through formation of talc or cellulose granulomas in lung tissue.[9]

HIV positivity was significantly higher in the study group than that in the general population. It is interesting to note that three of the HIV-positive patients were previously in good health and asymptomatic at the time they contracted pneumonia. Common bacterial infections have been reported as the most frequently encountered pulmonary problem in drug users.[10] It may be postulated that T-cell dysfunction is manifested very early by impaired ability to encapsulate gram positive organisms, thus increasing a patient's susceptibility and morbidity to pneumonia.

Modern medical therapy has continued to suppress morbidity and mortality in patients with antepartum pneumonia. However, the increasing incidence and severity of pneumonia in pregnancy requires greater use of fixed medical resources and funds to maintain a low complication rate. The etiologic agents involved in pneumonia do not seem to have changed significantly. The epidemiology and pathophysiology of the disease have been altered by changing characteristics of the obstetric population. More pregnant women are susceptible to community-acquired pneumonia today because of chronic medical conditions, cocaine addiction, and HIV positivity. The clinician faced with such a patient must act quickly and aggressively to prevent significant maternal or obstetric complication.

Ultrasonographic fetal weight estimation by an integrated computer-assisted system: Can each laboratory improve its accuracy?

Howard O. Thompson, MD, Cynthia Casaceli, BS, and James R. Woods, Jr., MD
Rochester, New York

Estimated fetal weights from 1684 cases with singleton, live infants born within 7 days of an ultrasonographic examinations were compared with their birth weights, which ranged from 520 to 5920 gm. Estimated weight calculated from Shepard's equation produced a linear relationship of birth weight against estimated weight with an intercept and slope of 209.5 gm and 0.929. Overall, 75% of the estimated weights were within 15% of the actual weight. A separate regression model that used the same variables from Shepard's equation failed to improve the comparison between estimated and actual weights. All cases were reevaluated with multiple regression modeling. Various examination-to-birth intervals were analyzed; intervals ≤3 days appeared optimal. The best equation increased the percent of cases that were within 15% of the actual birth weight to 80%. The plot of birth weight against estimated weight had an intercept and slope of 33.1 gm and 0.994. Unlike Shepard's equation, the best equation was not statistically different from the ideal one-to-one relationship between estimated and actual weight. When the new equation was applied to an additional 339 new cases, equally accurate results were obtained. Customizing a laboratory's ultrasonographic weight estimation equations may be necessary to obtain the best estimate of fetal weight. (Am J Obstet Gynecol 1990;163:986-95.)

Key words: Fetal weight estimation, computer analysis

Obstetrics has changed from validating the accuracy of ultrasonographic parameters by clinical dating criteria to validating the accuracy of the last menstrual period by an ultrasonographic examination.[1] With improving neonatal survival and increasing reliance on ultrasonography for clinical management, it is necessary to know the accuracy of ultrasonographic weight predictions. Several authors have proposed equations for estimation of fetal weight but few are based on more than 100 patients,[2-5] including some equations for fetal weight estimation that have become standards.[6-8] Many institutions use published weight estimation equations to calculate fetal weights. When Shepard's equation of weight estimation was compared between New Haven, Connecticut, and Dallas, Texas, different coefficients were needed to ensure the best correlation between the estimated weights and the birth weights for the two populations.[9] The purpose of this study was to evaluate the accuracy of our ultrasonographic fetal weight estimations by comparing them with actual birth weights to derive an institutional equation for ultrasonographically estimating fetal weight.

Methods

This study included all singleton pregnancies without congenital fetal abnormalities delivered between January 1983 and September 1989 at Strong Memorial Hospital, Rochester, New York, within 7 days of an ultrasonographic examination performed in our Perinatal Ultrasound Laboratory. These cases were used to determine the accuracy of ultrasonographic fetal weight estimation. Cases with complete ultrasonographic parameters (abdominal circumference [AC], biparietal diameter [BPD], and femur length [FL]) were included in the second part of the study to determine our population's best equation for fetal weight estimation. This equation was confirmed again by performing the calculations as a true cross-sectional study.

Each ultrasonographic examination was handled as an independent estimation. All examinations were performed with either a Technicare 280SL or a Corometrics 650. Multiple measurements were made for each parameter (BPD, AC, FL) with a Summa/IBM Digital Image Quantification System. For each measurement the program, written by the Perinatal Computer Center staff, checks the calibration and calculates the mean, standard deviation, and deviation from the mean for

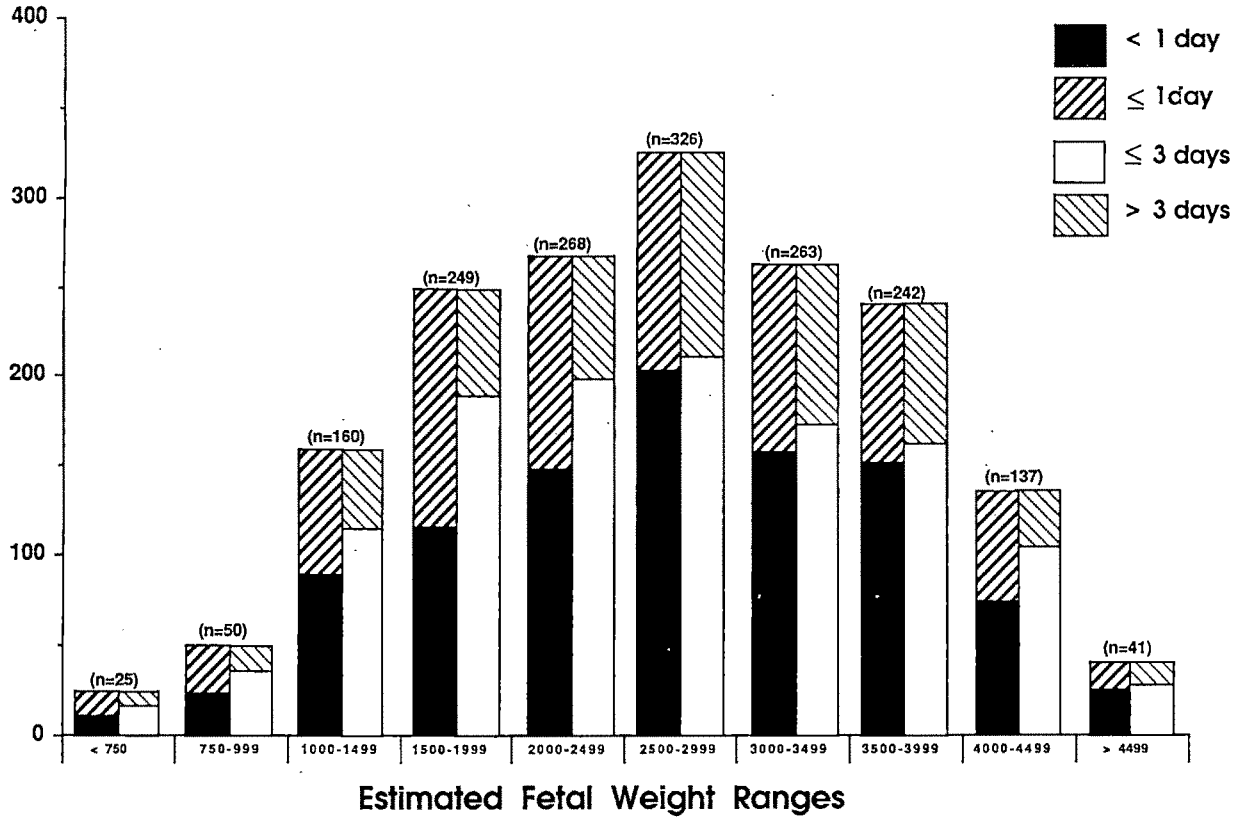

Fig. 1. Distribution of the total population (≤7 days) that has been subdivided by the examination-to-birth interval. Note the ≤1000 gm group has been subdivided by 250 gm intervals rather than 500 gm.

that parameter. The weight was estimated with mean AC and BPD in Shepard's equation (equation 1): Log_{10} (estimated weight) = − 1.7492 + 0.166/(BDP) + 0.046(AC) −2.646(AC × BPD)/1000.[6] The program does not calculate an estimated weight that is based only on abdominal circumference or in the absence of a normal head shape (cephalic index between 0.7 and 0.86). All measurement means and calculated values are stored in the Obstetrical Ultrasound Database. The delivery data were entered into the Perinatal Computer Database and merged with the Obstetrical Ultrasound Database.

The population was divided into groups by their estimated weights (Fig. 1), and by the examination-to-birth interval. The total population and groups were divided by the absolute value of the weight difference (|Estimate − Actual|) (Fig. 2, *A*) and the absolute percent difference (|Estimate − Actual|/Estimate × 100) (Fig. 2, *B*). The estimated fetal weight was used as the independent variable because it is the known variable before delivery and is used in clinical decisions. To determine if a shorter examination-to-birth interval would improve the predicted fetal weight, an analysis of the original population by examination-to-birth interval was performed twice, once between ≤1 day and >1 day and again between ≤3 days and >3 days. The ≤1-day group was a subset of ≤3-day group. The statistical analysis consisted of linear regression, χ^2 analysis, and unpaired *t* tests using the SPSS/PC+ 2.0 statistical package for the total population and subgroups.

To determine the institutional weight estimation curve, values for BPD, AC and FL, their multiplicative products, and their logarithmic transformations were entered into multiple regression computer models in a forward stepwise fashion. The same variables used in Shepard's equation (equation 1) were entered into a separate regression model, equation 2. The equations from the regression models were evaluated by adjusted coefficients of determination (adjusted R^2) and standard error. The new estimated weights from the models were compared with the actual birth weights using a paried *t* test and linear regression. The slopes of birth weight against estimated weight were compared using the *t* test of the regression coefficients with separate variances.[10] Comparisons of the slopes were made between the models, to equation 1, and to the ideal one-to-one relationship of the actual and estimated weights. This comparison was made for the total pop-

ulation and between the two examination-to-birth intervals (Table I). Further statistical analyses were performed on the estimated weights from the equation that had the best correlation between actual and estimated weight, based on the coefficient of determination (R^2), slope, and standard error of the slope.

To evaluate the hypothesis that the new weight estimation equation would represent our population better than Shepard's equation (equation 1), patients who were delivered at Strong Memorial Hospital within 7 days of an ultrasonographic examination, between October 1988 and May 1989, were evaluated prospectively. Those cases with complete ultrasonographic parameters meeting the same requirements as the initial population underwent weight estimates with Shepard's equation and our best new equation, equation 5. This population was evaluated and a full statistical analysis was performed on each set of estimates as in the initial population.

Results

The Perinatal Computer Database initially identified 1761 consecutive cases that met the study criteria. There were 1194 cases delivered within 3 days of an examination, including 706 cases born within 1 day. The birth weights ranged from 520 to 5920 gm, with a mean of 2704 ± 23.5 gm (mean ± SEM). The estimated weights, calculated from Shepard's equation, ranged from 556 to 6309 gm (mean, 2694 ± 23.8 gm). The mean absolute differences by weight and percent were 271 ± 5.48 gm and 10.51% ± 0.20%.

The distributions of the absolute differences in percent and grams differed significantly from one estimated weight group to another (X^2; $p = 0.002$ and $p < 0.0001$, respectively) (Fig. 2). The actual birth weights were more often within 100 gm of the estimate at the lower weights than at the higher weights (Fig. 2, *A*). Although the distribution of the absolute percent difference was statistically significant for the weight groups (Fig. 2, *B*), the overall distribution was more symmetric than the absolute weight differences (Fig. 2, *A*), which allowed for easier comparisons between weight groups.

There was a significant linear relationship between birth weight and ultrasonographically estimated weight (equation 1, Table I) with a slope of 0.929 and an in-

tercept of 209 gm (p < 0.0001). This relationship was statistically different from the ideal slope of 1 and an intercept of 0 for ≤1-day, ≤3-day, or ≤7-day examination-to-birth intervals (t = 6.13, 7.87, and 7.25, respectively).

The power analysis indicated there was a 99% probability of detecting a 2% difference between the estimated and actual weights or a difference in the slope of 0.016 for these two variables at an alpha error of p = 0.05. Although a 2% difference in the fetal weights was easily detectable, the probability of detecting a 100 gm absolute difference of an alpha error of 0.05 was 84.8%.[10] A 2% difference in fetal weight is not clinically significant, but a 100 gm difference may be clinically important. This indicated that absolute percent difference may be a more sensitive expression of the differences between the actual and estimated fetal weights over a wide range of weights.

When absolute weight differences were compared by examination-to-birth interval, only the ≤3-day/>3-day pairing had a significantly different distribution (χ^2; p = 0.0093). This observation suggests that the examination-to-birth interval may influence the predictive value of the ultrasonographic estimates. However, both the ≤1-day and ≤3-day intervals had greater percentages of lower weight infants with smaller absolute difference (Figs. 3, *A* and 4) than >1-day and >3-day intervals. This distribution difference can be compensated for by use of absolute percent differences. There was no difference between either of the interval pairings when the difference was expressed as absolute percent difference (Fig. 3, *B*). Furthermore, there were significant linear relationships between actual and estimated weights for all examination-to-birth intervals, but there was no statistical difference between these slopes (Table I). This indicates the data can be further analyzed without regard for the examination-to-birth interval if the absolute percent difference and slopes are used in the analysis.

To compare the regression models in the second part of this study, 77 cases were excluded because of unreported femur length. The initial statistical analysis was recalculated (n = 1684) without any appreciable changes in the means, distributions, or significance (Table II). When several serial examinations were deleted for a true cross-sectional study, the statistics from

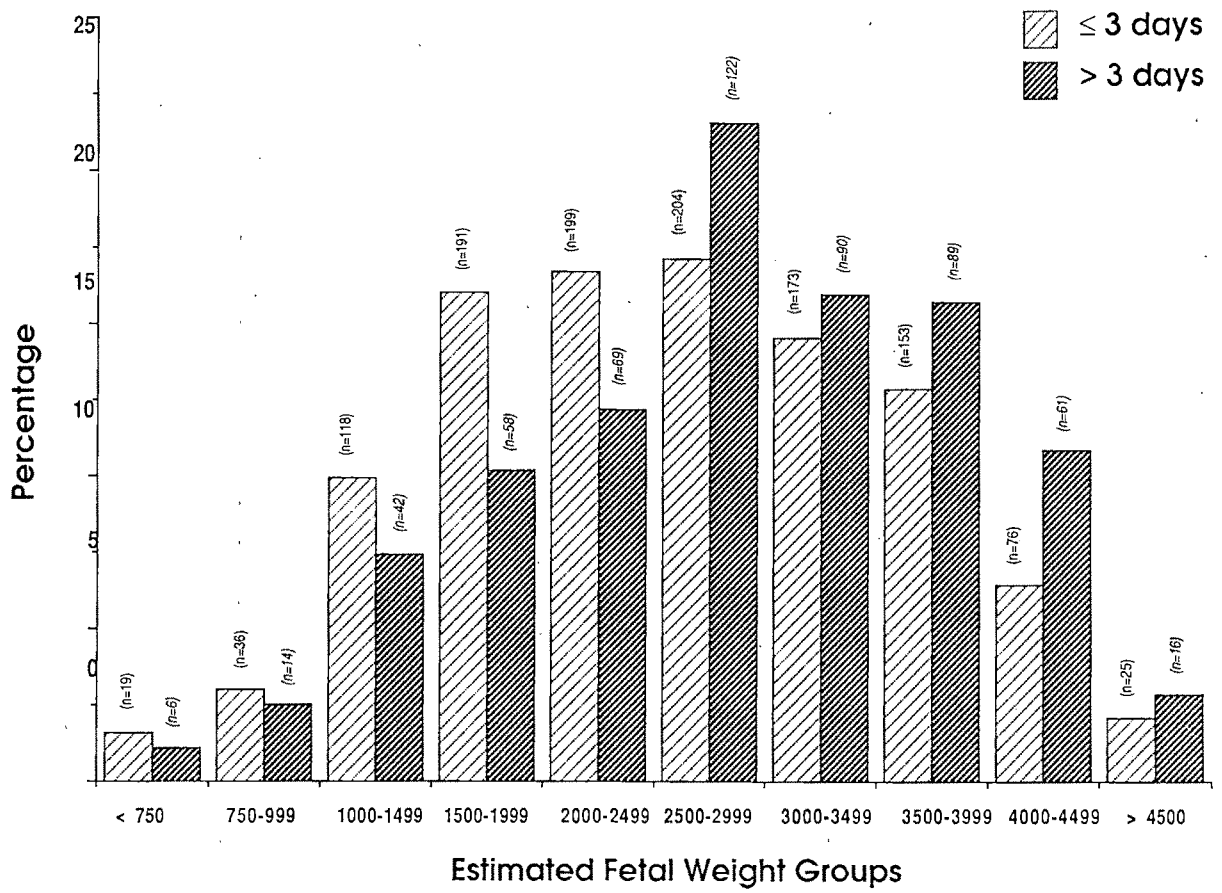

Fig. 4. Population distribution by estimated fetal weight groups. It has been subdivided by examination-to-birth intervals of ≤3 days and >3 days.

the remaining 1560 cases only differed in the third or fourth significant figure from the 1684 cases.

Although many more linear and nonlinear models were constructed, only those that used femur length, BPD, abdominal circumference, and the logarithm of the weight approached an adjusted R^2 value of 0.924. Only for these cases were birth weights regressed against the new estimated weights (Table I). The expected values for the models were calculated to obtain the new estimated weights. A full statistical analysis was performed only on equation 5. It was the model that had a slope closest to 1, a larger R^2 value, and a lower standard error of the slope for the plot of birth weight versus estimated weight than equation 1. More importantly, this new equation was not statistically different from the ideal slope of birth weight against estimate. The improved slope of birth weight against estimated weight was statistically different from the original (equation 1; $p < 0.0001$) or modified Shepard's equations (equation 2; $p < 0.0001$ and $p = 0.014$, respectively).

In comparison with equation 1, the estimates from equation 5 resulted in 5% more (84 additional) fetuses with an absolute percent difference of ≤10%, (χ^2; $p < 0.0001$). The mean absolute percent difference was significantly reduced to 9.46% (paired t test, $p < 0.001$). This new model could detect a difference in distribution of the absolute percent difference between ≤3 days and >3 (χ^2; $p = 0.0107$). This was not possible with the original equation. No significant difference was found when the data were analyzed by ≤1-day or >1-day intervals (χ^2; $p = 0.285$).

The prospective study identified an additional 339 cases with complete ultrasonographic parameters. There were 218 cases delivered within 3 days of an examination, including 147 cases delivered within 1 day. The birth weights ranged from 240 gm to 4885 gm (mean, 2713 ± 56.1 gm). The fetal weights estimated by equation 1, Shepard's original equation, ranged from 283 to 5014 gm (mean, 2696 ± 56.3 gm). The mean absolute percent difference was 9.85% ± 0.43%. Neither the means nor the slope of birth weight against estimated weight from the prospective study were statistically different from equation 1 in the retrospective study.

To confirm whether equation 5 should replace the existing equation, a series of paired and unpaired t tests were performed only on the prospective cases. There

*Comparison with the t test of the regression coefficient. When the slopes of equations 1 and 5 were compared, a t value of 1.638 ($p = 0.10$) was obtained.

were no statistical differences between the estimated weight and the mean birth weight by either equation. The mean absolute percent difference of equation 5, 8.77% ± 0.38%, was significantly lower than equation 1 in the prospective study ($p < 0.001$). The absolute percent difference was consistently not significant in unpaired t tests between the interval pairings. Overall, 5.6% more cases had smaller differences between actual and estimated weights, and 4.8%, or 16 more cases, had an estimate within 10% of actual weight. This result was consistent with the retrospective evaluation.

The differences between the slopes of birth weight against the estimate for equation 5 and equation 1 approached significance ($t = 1.64$, $p = 0.10$). However, when the two equations were compared with the ideal, equation 5 was not significantly different ($t = 0.721$, $p = 0.47$), while the original equation, equation 1, was significantly different from ideal ($t = 2.96$, $p = 0.003$). There was also no difference between the longer and shorter intervals for each equation (Table III). Not surprisingly, for both equations, the shorter interval groups (≤1 and ≤3 days) had slopes and coefficients of determination (R^2) closer to one than their longer interval.

These comparisons of differences and slopes established equation 5 as the best equation for our population. It also established the absolute percent difference as the best comparison of the actual and estimated weights. This finding was consistent with the retrospective evaluation.

Comment

This study evaluated the accuracy of our current ultrasonographic weight estimation equation and developed an equation with statistically lower mean differences of estimated to actual birth weight. This equation has coefficients of regression and determination closer to unity with a smaller intercept than the original equation. An adjusted R^2 value of 0.925 from equation 5 was superior to most of the original work for the "standard" equations.[6-8] This study was initially performed as a large retrospective analysis, confirmed as a true cross-section study with a prospective evaluation of an additional 339 cases. This analysis was made possible because our recording system was an integral part of our ultrasonographic measuring system. Without the integration of the Perinatal Computer Database and the Obstetrical Ultrasound Database, this evaluation would have been difficult.

Although not statistically different in both the retrospective and prospective portions of our study, the shorter examination-to-birth intervals had better linear comparisons and lower differences between actual and estimated weights. For most equations the shortest examination-to-birth interval (≤1 day) had a slope and intercept closest to ideal, followed by the group with an interval ≤3 days. Based on the comparison of the slopes and intercepts of birth weight against the estimated weight, there may be an optimal examination-to-birth interval. When the population was divided by cases delivered within 3 days or more than 3 days, there was a significant difference in the absolute percent difference distribution in the retrospective evaluation, but when the population was reclassified by those that delivered within 1 day or more than 1 day there was no significant difference. The loss of significance when the population was divided by intervals ≤1 day or >1 day may be due to those cases that were born 2 and 3 days after an examination, and whose estimate may be equally accurate, being reclassified into the longer interval group. In addition, in both portions of the study and for both equations 1 and 5, the slope of the ≤3-day interval groups were mirror images of the total population but with lower intercepts. This study indi-

cates than an examination-to-birth interval of less than or equal to 3 days may be optimal.

This study raises several questions concerning ultrasonographic fetal weight estimation. The first question regards the best method to present differences between the estimated and actual weights. The use of actual weight or percentage differences is unsatisfactory because overestimations and underestimations cancel each other. The use of absolute weight differences in grams is only marginally satisfactory as a clinical tool. A 150 gm difference for a 3000 gm infant is a much smaller relative difference than for a 1000 or 500 gm infant. The absolute percent difference remains as the only term that makes clinical sense. It can be uniformly used with all weights.

The next question is which weight should be used as the denominator to calculate absolute percent difference. Previous authors have used the actual birth weight as the denominator.[2-17] This may be mathematically correct for a retrospective study but is less useful clinically. The difficulty with use of a percent difference based on actual weight is that it is an unknown until after birth. It is more practical to have an error range for a known number, the estimated weight, than for an unknown, the actual weight. For the absolute percent difference to be clinically relevant, it is necessary to use the prenatally known variable, estimated fetal weight, as the denominator.

The third question of ultrasonographic weight estimation concerns the weight equation itself. Although our initial equation gave a slope of birth weight against estimate within the range of the existing papers (0.914 to 1.0061),[11-13] it was statistically different from the ideal relationship. The same combination of variables in the original Shepard's equation (equation 1) were entered separately into a multiple regression model; this resulted in equation 2 with completely different coefficients for the variables than the original Shepard equation. This makes at least three forms of Shepard's equation, all with different coefficients for the same variables and each derived from different populations (New Haven, Dallas, and Rochester[13]), that yield inferior weight estimates compared with our best equation, equation 5. It appears that regional population differences may account for the number of studies that expound on finding a "new" ultrasonographic weight estimation equation.[14-17] It is probable that each obstetric ultrasonography laboratory must develop its own estimation equation.[9]

The final question of fetal weight estimation addresses the concerns of previous authors about the need for separate estimation equations for large and small infants.[5, 11, 18-20] These studies suffer from small numbers of subjects and poor controls. The largest number of small infants is 70 in a study by Sabbagha et al.[18] It is also the only study with normal weight controls, but their weight estimation equation uses the gestational age as one of the terms of the equation.[18] Since gestational age is frequently an ultrasonographic estimation, its use in a weight estimation equation may render their equation less accurate than an equation completely derived from the primary ultrasonographic measurements. Examination of Fig. 2, *B*, gives the impression that our population could be divided into two groups at 2500 gm. When separate multiple regression models were developed for each group, the adjusted R^2 value from equation 5 for the total population, 0.926, remained superior to either of the adjusted R^2 values for the ≤2500 gm model, 0.884, or the >2500 gm model, 0.652. This indicates that our population is best represented by a single weight estimation equation and not separate equations for the different weight ranges.

Overall this study has shown that there is a need for a routine evaluation of the accuracy of a laboratory's ultrasonographic fetal weight estimation. It also indicates that this evaluation cannot stop at mere comparisons of birth weight to estimated weight to obtain an absolute percent difference but must include an evaluation of the laboratory's weight estimation equation at regular intervals. Because each population and each ultrasonographic laboratory is dynamic, this equation may require changes to reflect the changes in the laboratory's personnel and population. Finally, a well-integrated ultrasonographic and delivery database is important for evaluation of this methodology on a regular basis.

Ultrasonographic assessment of intestinal damage in fetuses with gastroschisis: Is it of clinical value?

Roger R. Lenke, MD, Wayne H. Persutte, BS, RDMS, and Joanne Nemes, RNC
Toledo, Ohio

In cases of gastroschisis detected prenatally it has been proposed that ultrasonographic criteria may play an important role in the decision for early delivery. We evaluated five cases of gastroschisis diagnosed before birth and found a correlation between prenatally detected small bowel dilatation and severe intestinal damage. However, from the limited data available these in utero measurements seem to be ineffective as indicators for delivery intervention (1) because not all fetuses with bowel dilatation have postnatal evidence of intestinal damage, (2) because some infants with intestinal damage and a poor postnatal outcome may show no in utero evidence of bowel dilatation, (3) because initial bowel dilatation may occur before a gestational age when lung maturity is achieved, and (4) because, in those cases in which bowel dilatation did correlate with intestinal damage, the bowel was already beyond the point of salvage and the infant required bowel resection. (AM J OBSTET GYNECOL 1990;163:995-8.)

Key words: Fetal gastroschisis, bowel dilatation, ultrasonography

In 1988 Bond et al.[1] published a series of 11 cases of gastroschisis diagnosed before birth and correlated the clinical outcome with the ultrasonographic appearance of the eviscerated bowel. They noted that the prenatal presence of small bowel dilatation[2] and mural thickening correlated with severe intestinal damage and a poor postnatal outcome. They subsequently concluded: "now that reliable sonographic criteria of severe intestinal damage have been defined, the decision to deliver early can be restricted to those fetuses with bowel dilatation and mural thickening." We prospectively evaluated our series of cases of prenatally detected gastroschisis to determine whether this conclusion was justified.

Case reports

Case 1. A 19-year-old white woman (gravida 2, para 0, [one elective termination]) was referred after multiple episodes of premature labor. Our initial ultrasonographic examination at approximately 32 weeks' ges-

tation showed the presence of an abdominal wall defect consistent with gastroschisis. Evaluation of the fetal bowel showed normal-appearing bowel. Fetal lung maturity was documented by amniocentesis and the mother underwent an uneventful delivery by cesarean section. A female infant weighing 1870 gm was delivered with Apgar scores of 5 at 1 minute and 7 at 5 minutes. The fetus had a stormy postdelivery course and required multiple surgical procedures and subsequently died after approximately 3 months as a result of complications of the gastroschisis.[5]

Case 2. An 18-year-old white woman (gravida 1, para 0) was first referred for evaluation because of an elevated maternal serum α-fetoprotein. Initial ultrasonographic examination showed a fetus compatible with 18½ weeks' gestation and the presence of gastroschisis. Serial evaluations showed no evidence of fetal bowel distention but did show progressive intrauterine growth retardation. Evaluation at 34½ weeks' gestation showed significant bowel dilatation and delivery was accomplished at 35 weeks' gestation after fetal lung maturity was documented by amniocentesis. A female infant weighing 2019 gm with Apgar scores of 9 and 9 at 1 and 5 minutes, respectively, was delivered by cesarean section. Primary closure of the defect was accomplished without complications and the infant was discharged on the twenty-eighth day of life.

Case 3. A 24-year-old white woman (gravida 3, para 1) was initially referred because of an outside ultrasonogram indicative of a fetal abdominal wall defect. Our initial evaluation at 21 weeks' gestation showed the presence of gastroschisis. Multiple evaluations throughout the pregnancy did not show any evidence of bowel dilatation or mural thickening. Delivery was accomplished by cesarean section at 37 weeks' after documentation of fetal lung maturity by amniocentesis. The infant was male with Apgar scores of 8 and 9 and a birth weight of 2825 gm. The abdominal wall defect was easily closed and the infant had a benign postoperative course and left the hospital on the twenty-second day of life.

Case 4. A 21-year-old white woman (gravida 1, para 0) was initially referred for evaluation because of an outside ultrasonogram that showed a questionable fetal abdominal wall defect. Our initial evaluation showed a fetus compatible with 20 weeks' gestation and the presence of gastroschisis. Ultrasonographic evaluations at 22 weeks' gestation and 25½ weeks' gestation showed normal-appearing fetal bowel. Ultrasonographic evaluation at 28 weeks' gestation showed significant fetal bowel dilatation. A repeat ultrasonogram at 32 weeks' gestation again showed fetal bowel thickening in at least one segment. At 34⅓ weeks' gestation there was an increase in the fetal bowel dilatation but fetal lung maturity testing did not show maturity. At approximately 36 weeks' gestation, the mother complained of decreased fetal movement and the fetal heart rate tracing showed the presence of apparent late decelerations. An amniocentesis documented fetal lung maturity and the infant was delivered by cesarean section. A female infant weighing 1880 gm with Apgar scores of 3 and 8 was delivered without complications. A primary closure of the infant's defect was accomplished after resection of a portion of the fetal bowel. The infant had feeding problems and was discharged home on the fifty-eighth day of life while treated by hyperalimentation.

Case 5. A 17-year-old white woman (gravida 1, para 0) was initially referred for ultrasonographic evaluation because of an elevated maternal serum α-fetoprotein level. Our initial evaluation showed a fetus at approximately 17½ weeks' gestation with gastroschisis. Follow-up ultrasonographic evaluations at 22, 25, 28, and 32 weeks showed no evidence of fetal bowel dilatation or mural thickening. There was a decline in fetal growth so that by the time the gestation was 32 weeks by last menstrual period and early ultrasonographic scan, the fetus had measurements consistent with only 28½ weeks' gestation. The patient was again evaluated at 34 weeks' gestation and at that time there was significant dilatation of several loops of fetal bowel. Fetal lung maturity was documented by amniocentesis and the patient subsequently underwent an elective cesarean section. A male infant weighing 1600 gm with Apgar scores of 5 and 7 was delivered. A primary closure of the defect was not possible, and a silo was created. At the time of reoperation there was evidence of necrotic bowel necessitating a bowel resection. The infant had a stormy neonatal course caused by complications of the gastroschisis and bowel resection and was hospitalized for >60 days.

Comment

We evaluated five cases of gastroschisis diagnosed before birth and correlated the clinical outcome with the ultrasonographic appearance of the eviscerated bowel. Three of the five fetuses had in utero evidence of bowel compromise as evidenced by bowel dilatation and increased mural thickness (Table I). Two of these infants subsequently underwent bowel resections and had extremely stormy postnatal courses. One of the infants with in utero bowel dilatation had a primary closure and a relatively benign postoperative course. Conversely, the only infant who died had no evidence of in utero bowel compromise detected by ultrasonographic evaluation. In our experience evaluation of bowel wall thickness did not prove useful. Although there was a tendency for mural thickness to increase with overall bowel dilatation, dilatation was more easily measured and had a better correlation.

Thus we agree with the data presented by Bond et al.[1] that the presence of prenatal small bowel dilatation and mural thickening correlates with severe intestinal damage and a poor postnatal outcome. However, we believe their conclusion that "the decision to deliver early can be restricted to those fetuses with bowel dilatation and mural thickening" is unjustified

on the basis of the available data.[4-8] From the limited data available these in utero measurements seem to be ineffective as indicators for delivery intervention for the following reasons. (1) Not all fetuses with bowel dilatation have postnatal evidence of intestinal damage. (2) Some infants with intestinal damage and a poor postnatal outcome may show no in utero evidence of bowel dilatation. (3) Initial bowel dilatation may occur before a gestational age when lung maturity is achieved. (4) In those cases in which bowel dilatation did correlate with intestinal damage, the bowel was already past the point of salvage and the infant needed a bowel resection. Therefore, until more data are accumulated, we believe the delivery of infants with gastroschisis should be based on documentation of fetal lung maturity or other evidence of fetal compromise (such as nonstress testing and contraction stress testing) rather than evidence of bowel compromise. Because bowel dilatation can occur late in gestation, the data may lend some support to the concept of more frequent ultrasonographic evaluation late in gestation or early delivery once lung maturity is documented.

These data also reiterate that even early delivery by cesarean section before labor does not guarantee a benign neonatal course.[9] Although it is unlikely that the actual physical mode of delivery changes the neonatal outcome, there still appears to be the need for a more thorough evaluation of the concept of preterm delivery to prevent the late development of bowel dilatation and the avoidance of bowel compromise as a result of labor (either with or without ruptured membranes). Until more data become available, we discuss the available literature with our patients and allow them to participate in the decision regarding mode of delivery. To date, most patients have chosen cesarean delivery.

Lack of specific placental abnormality associated with cocaine use

William M. Gilbert, MD, Christopher M. Lafferty, MD, Kurt Benirschke, MD, and Robert Resnik, MD

San Diego, California

Detailed gross and histologic examinations were performed on 13 placentas from pregnancies complicated by maternal cocaine use. There were no characteristic changes in placental morphologic features that would explain the increased morbidity associated with cocaine use. It is likely that cocaine exerts its deleterious effects through acute or chronic pathophysiologic changes rather than alterations in placental architecture. (Am J Obstet Gynecol 1990;163:998-9.)

Key words: Pregnancy, placenta, cocaine abuse

Cocaine use during pregnancy is associated with a marked increase in perinatal morbidity and mortality. The complications observed include intrauterine growth retardation, abruptio placentae, preterm delivery, preeclampsia, and fetal morphologic abnormalities that include the skeletal and urinary tract.[1-5] Chasnoff et al.[4] have demonstrated an increased incidence of abruptio placentae and alterations in the neonatal behavioral assessment scale even when cocaine use was limited to the first trimester of pregnancy.

Hertig[6] described certain distinctive placental vascular changes of subendothelial lipid-laden macrophages, fibrinoid deposition, and inflammation of arterial walls in placentas from cases of preeclampsia. Similarly, Dixon and Robertson[7] found abnormalities in placental vessels in patients with preeclampsia and chronic hypertension.

Previous studies from our laboratory[8] and others[9] have demonstrated that acute administration of cocaine results in profound uterine vasoconstriction and increases in uterine vascular resistance. The purpose of this study was to determine whether cocaine use during pregnancy might result in any characteristic morphologic changes in the placenta that might explain, in part, the associated pregnancy complications.

Methods

Patients were seen for labor and delivery care at the University of California, San Diego Medical Center between Jan. 1 and June 30, 1989; those who had not received prenatal care or were considered to be at risk for drug use were screened for illicit drug use. The urine toxicology screen identified multiple drugs and their metabolites including the amphetamine, barbiturate, cocaine, opiate, and phencyclidine classes of drugs.

A detailed history of drug use was obtained from the mother, and the delivery and newborn records were examined. All cases in which mothers reported a history of multidrug use or in which the drug screen was positive for drugs other than cocaine were excluded from the study. Gross and microscopic examinations of the placenta were performed by one of the authors (K. B.). The study cases were compared with a group of nonrandomly selected placentas from deliveries of similar gestational ages, in which cocaine was not used during pregnancy.

Table I. Outcomes of pregnancies complicated by cocaine use

Case no.	*Gestational age (wk)*	*Delivery*	*Birth weight (gm)*	*Complications*	*Placental abnormality*

C/S, Cesarean section; *Vag.,* normal vaginal delivery; *PTL,* preterm labor; *PTD,* preterm delivery; *PIH,* pregnancy-induced hypertension; *SGA,* small for gestational age; *PROM,* premature rupture of the membranes; *IUFD,* intrauterine fetal death.

Results

During the time period, 13 patients met the inclusion criteria and were included in this study. The characteristics of patients and pregnancy outcomes are displayed in Table I. Among the 13 patients, 9 infants were born preterm (<37 weeks), 5 sustained premature rupture of membranes, 5 had intrauterine growth retardation (<10th percentile birth weight for gestational age), 2 had preeclampsia, and 2 had meconium staining of the amniotic fluid or meconium aspiration syndrome.

No specific gross or microscopic placental changes were observed. Although the placentas from pregnancies complicated by premature rupture of membranes revealed evidence of chorioamnionitis, the findings were not different from those of placentas of pregnancies with premature rupture of the membranes but without cocaine use.

Comment

Chasnoff et al.[4] reported that women who used cocaine only in the first trimester of pregnancy still had an increased incidence of abruptio placentae. They proposed that early cocaine exposure alone might cause an abnormality in the placenta that would explain the increased incidence of premature separation observed later in pregnancy. Our study detailed examination of the placentas of cocaine-using women revealed no specific abnormalities, and this new evidence would not support such speculation.

Although our study focused on gross and morphologic placental examination, we also observed a high pregnancy complication rate, which has been previously reported.[1-5] Moore et al.[8] examined the hemodynamic effects of cocaine exposure on the ovine maternal and fetal circulations. They found a rapid and highly significant increase in both maternal and fetal arterial blood pressure, as well as a marked decrease in uterine blood flow. These changes persisted for 15 minutes after injection into the maternal circulation and were thought to be secondary to inhibition of norepinephrine reuptake at the nerve terminals.[8] Similarly, Woods et al.[9] confirmed these findings. These acute hemodynamic changes brought about by cocaine use are likely to result in acute vasoconstriction in humans.

In this study we were unable to find any specific morphologic alterations in the placenta that could explain the complications associated with cocaine use in pregnancy. These findings, combined with previously reported physiologic alterations, would support the concept that the fetal morbidity associated with cocaine use is a consequence of pathophysiologic changes rather than morphologic ones. The reason why these pathophysiologic changes are not manifested in morphologic changes is completely unknown.

TRANSACTIONS OF THE FIFTY-SECOND ANNUAL MEETING OF THE SOUTH ATLANTIC ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Retrospection and prospection

Presidential address

Allan G. W. McLeod, MD
Miami, Florida

It is with considerable pride, great appreciation, and some trepidation that I stand here to present this address. I cannot but recognize that you have elected me to a distinguished group of persons that contains names such as "Daddy" Ross, Bayard Carter, Frank Lock, Charles Collins, and many others who, each in his own way, has contributed much to our specialty and to this Association. Quite a tribute to a foreign medical graduate!

I am sure that each president has considered a wide range of subjects for his address before arriving at a final decision. I found myself reflecting on the circumstances that brought me to this side of the Atlantic Ocean to spend half a lifetime in South Florida, with regard to events that have influenced my career and the practice of our specialty over the years and to changes most likely to affect us in the future. The decision was ultimately made after a recent Sunday at Plymouth Church in Coconut Grove when our Minister "Woody" Hasty in his sermon alluded to "the lift of a long look back" and its value in life. The only problem is that some of us are beginning to realize we have a very long way to look back! I would like to share a few of my reflections with you. We are told that history repeats itself and the truth of that statement is surprisingly obvious as we look back.

I had the good fortune to be born into a medical family and to be reared and educated in that small country north of the river Tweed where friendliness and concern for the individual are almost a part of the national character. My first effort in clinical diagnosis at around age 7 years brought me 3 months in a hospital. I complained to my grandfather, a general practitioner, that I did not feel well and had a sore throat and, having taken a look at it, I informed him that my throat was white. Within an hour I had received a full dose of diphtheria antitoxin and was lying flat on my back in the hospital.

Another recollection was of that same white-haired gentleman coming home after making house calls with my father, also a general practitioner, discussing an amazing occurrence. For the first time they had had the opportunity to treat a patient who had pneumonia with "M&B 693" a sulfonamide and the patient had rapidly recovered. Penicillin was not yet available for clinical use. We have indeed come a long way in medicine in a relatively short time span. The seeds of my interest in obstetrics were probably sown in the same manner. My father and grandfather would discuss midwifery problems between themselves and with the local nurse midwife and with the consultants who came from the teaching hospital on domiciliary consultations.

I was fortunate enough to become a medical student at Glasgow University with its long tradition of excellence in medicine. My guess would be that few of you can say that your university celebrated its 500th anniversary while you were a student. I might add that its tradition of excellence in our specialty has continued under the leadership of one of the guests with us today.

The Hunterian Museum at Glasgow University memorializes the major contributions of the brothers John and William Hunter to medical knowledge. More interesting to us perhaps is the work of their contemporary William Smellie to whom I shall refer later. Students at the Royal Infirmary attended lectures in The

Lister Lecture Theater named in memory of Lord Lister who advanced the principles of antisepsis in surgery. The members of this association should readily recognize the name Munro-Kerr, a former professor of midwifery at Glasgow who pioneered the low transverse incision in the uterus for cesarean section that continues to have a major impact on our current practice.

The emphasis on clinical bedside teaching was strong. Students considered themselves to be on the cutting edge. Cross-sectional anatomy was being taught and ultrasonography was in its infancy, but little did we realize the impact it would have on our practice. We had to establish the diagnosis with clinical acumen and without the sophisticated ultrasonographic equipment available to today's obstetrician.

Ian Donald in Glasgow and Louis Hellman in New York were pioneering techniques of diagnostic ultrasonography that have revolutionized the practice of obstetrics by providing us with access to the fetus in utero. We now have the ability to assess amniotic fluid volume, fetal maturity, growth and normality, lie and presentation, as well as the location and maturity of the placenta. The biophysical profile has been developed to assess fetal well-being with ultrasonography.

As the equipment has become more sophisticated, chorionic villus sampling at 9 to 12 weeks' gestation has become a viable alternative to the standard amniocentesis at 16 weeks' gestation for genetic diagnosis. Periumbilical blood sampling techniques have provided us with direct access to the fetal vascular system for purposes of diagnosis and treatment. The use of ultrasonography has become such an integral component of obstetric and gynecologic practice it should be handled by the obstetrician-gynecologist rather than the radiologist, with high-quality equipment available on the labor delivery unit 24 hours a day for on-the-spot decision making.

Ultrasonography is also playing an increasingly important role in gynecologic practice. Introduction of the vaginal transducer has enhanced its applicability in such areas as in vitro fertilization, diagnosis of ectopic pregnancy, localization and assessment of pelvic masses and of ovaries in postmenopausal women. Its use is being explored in evaluation of urinary incontinence. Whereas more experience with the use of ultrasonography must be provided in residency training, difficult diagnostic and special procedures should be handled by those obstetricians and gynecologists with special expertise in the field. In addition, ultrasonography is being widely used to complement mammography in evaluation of the breast mass.

My interest in midwifery, or obstetrics as we now term it, began early and was further stimulated by exposure as a student and resident to excellent clinicians and to the writings of the man described in a biography by R. W. Johnson: *William Smellie—The Master of British Midwifery.* I was fortunate enough to have obtained a reprint of one of Smellie's publications: *A Sett of Anatomic Tables,* which was originally published in 1754.[1] The accuracy of the illustrations is incredible as is the clarity of the descriptive text. Equally impressive is the frequency with which many of the principles he espoused almost 250 years ago remain applicable in present day practice. If you have never experienced the opportunity to read some of his work your knowledge in the field of our specialty is incomplete.

William Smellie was born in Lanark on the Clydeside, trained in Glasgow as a medical apprentice to Dr. John Gordon, and opened his practice in Lanark in 1720. He became a member of the Faculty or Physicians and Surgeons in Glasgow in 1733 and was eventually granted his MD degree in 1745. He began the practice of obstetrics despite "stern opposition and offensive epithets" by the local midwives. Subsequently, he moved his practice to London where he established a worldwide reputation as a teacher of doctors and midwives, and unequivocally demonstrated the value of training and experience in obstetrics. Smellie was a giant in his own time and has continued to influence obstetric practice up to the present. Even in London, however, he had his opponents including the midwife who described him as "a great horse-godmother of a he-midwife!" I think it is safe to say that whereas some rancor and difference of opinion still exist, we have for the most part a much more collegial relationship with nurse midwives today. Having worked closely with nurse midwives over the past 35 years I remain convinced that obstetricians, family physicians, and nurse midwives will have to cease bickering, stop the petty jealousies, and agree to join forces and work together as a team if we are ever to be able to render obstetric care to all in this country who need it, and to significantly reduce perinatal and infant mortality.

In 1847 another Scot, James Young Simpson,[2] introduced modern anesthesia in obstetrics. Initially he used ether and later in the same year introduced chloroform for the relief of pain in childbirth. He met opposition from physicians (does that sound familiar?), the public, but particularly the Calvinistic clergy who described him as a heretic, blasphemer, and agent of the devil. They dueled with biblical quotations, but he stood his ground and prevailed.

Six years later John Snow administered chloroform to Queen Victoria at the birth of her eighth child, but the editor of the *Lancet* journal opposed publication of the report. *Lancet* finally reported the use of chloroform at a subsequent delivery in 1857, which was tantamount to a seal of approval by the medical establishment. Controversy did not disappear, even 109 years later in the

mid-1950s Pope Pius XII expressed approval of methods to relieve pain during labor and delivery.

Anesthesia became significantly related to the occurrence of maternal mortality, which in time led to the delineation of obstetric anesthesia as a special field with documented training in this field being required for certification by the American Board of Anesthesia. Anesthesiologists in some instances are now limiting their practice to obstetric anesthesia. In consequence we have seen major advances, especially in techniques of regional anesthesia which was introduced only as recently as the 1940s. Caudal and spinal techniques have for the most part given way to epidural analgesia and anesthesia. Over the years complications of anesthesia have unfortunately remained a significant cause of maternal mortality after delivery by cesarean section, hence epidural (or spinal) has become the procedure of choice in as high as 90% of abdominal deliveries. Newer epidural techniques of labor analgesia involve continuous infusion of a weak local anesthetic agent plus a narcotic (fentanyl citrate). This affords less motor block and more continuous pain relief and holds great promise.

Improved postoperative pain relief has been afforded by continuous epidural block; however, use of the patient-controlled analgesia pump is probably a much more practical approach that gives the patient an element of control over her own pain relief. Other than local nerve blocks, less and less anesthesia is now being rendered by the obstetric attendant.

Equally important has been the spread to this country of the philosophy espoused by Grantley Dick-Read in the 1940s with women expressing their desire for a more "natural" birth, if one may use that terminology. While in training I worked in the same obstetric unit as the midwife daughter of Helen Herdman, the physiotherapist who along with Grantley Dick-Read pioneered "childbirth without fear" or as it later came to be know "natural childbirth." Even in the 1950s prenatal classes were being offered and most women had a spontaneous delivery. With this background it was surprising to find on my arrival in Florida that general anesthesia was frequently induced and forceps were applied for a "normal" delivery.

The explanations given to me for this were multiple, but for the most part were not particularly convincing. It took almost 10 years for the winds of change to start as a light breeze and a further 5 to 10 years for more general acceptance, particularly by obstetricians. The positive aspect of the change has been that for the most part women are now much better informed with regard to childbearing. The expectant father can be equally involved throughout pregnancy and participate rather than being assigned to "boil the water" at the time of delivery. The resistance from obstetricians as one looks back is almost characteristic. Perhaps one can be persuaded to believe that we as a group are somewhat egotistical individuals, some of whom were concerned at the concept of loss of control or had genuine concern of conflict and resisted the presence of family members who were often present when births occurred in the home. Hospitals established rules that in retrospect often appeared more for the benefit of the staff than of the patients. It seems strange that hospitals and many in the medical profession after many years have had to reinvent "family-centered childbirth" in the hospital setting. The same hospitals are now actively marketing their ability to provide this type of care. By recruiting the expectant mother they hope to "capture" the rest of the family. Likewise, obstetricians, to a great degree in response to the pressure by their patients, have become more responsive. For much too long physicians and hospitals simply rejected or ignored these requests. The result was an increasing demand for delivery at home. Most American-trained obstetricians have no experience in this area. Those of us who have had the opportunity to conduct deliveries in the home have learned it can be a very fulfilling experience when no complications arise. However, we have experienced at first hand the problems that may arise even with full backup by a well-equipped obstetric flying squad and know that there is a better alternative. It has been clearly demonstrated that a birth center approved by the National Association of Childbearing Centers or delivery in a hospital that provides family-centered childbirth coupled with early discharge if so desired, are certainly safe and preferable alternatives for appropriately selected patients. A similar philosophy appropriately amended can also be used for women in the tertiary care centers. Despite the continued reluctance of many obstetricians, early discharge is increasingly a reality for all our patients mandated by insurance companies, federal programs, and the affordability of care to private patients, especially in the lower- and middle-income groups. It is disappointing that so many obstetricians have had to be dragged along reluctantly instead of responding objectively and positively to the desires of our patients when it was safe to do so. Equally, the reticence to look at changes in practice occurring in the United Kingdom, Europe, and the Antipodes, to evaluate them, and to adopt them on a more timely basis is hard to explain. A classic example is vaginal delivery after cesarean section, which was a regular practice in Glasgow when I came to the United States in 1960.

Infection as a complication of delivery remains our constant companion. Joseph Lister proved that when bacteria were kept away from the operation site, invasive surgery was possible. Oliver Wendell Holmes attributed puerperal sepsis to infection carried by the

attendant and Semmelweiss in Vienna scientifically proved him to be correct. A profound drop in the obstetric death rate occurred when Semmelweiss insisted on preoperative hand washing with soap and water and soaking the hands in chlorinated lime solution. Almost as one might expect he was opposed by his chief, attacked by his contemporaries, and eventually was forced to leave Vienna. Even his book published 10 years later met opposition—a familiar theme in the history of medicine! The problem of surgical infection was approached by Lister from a different direction. He was luckier in that he held a prominent appointment, worked in an intellectual climate, and was able to prevail in the face of criticism.

He observed that intact skin over a fracture usually resulted in healing of the bones without difficulty; however, when the skin was broken infection developed and pus would drain. After witnessing infections at other operations he postulated the presence of "disease dust" in the air. He recognized the relationship of his findings with Pasteur's work and approached the problem by spraying carbolic acid over the surgical site. A procedure that he subsequently reported in *Lancet.*

Needless to say he also met with disinterest and opposition on both sides of the Atlantic. In a historical review Lyons[3] ascribed to Samuel Gross, one of the leading American surgeons of the day, the statement "little if any faith is placed by any enlightened or experienced surgeon on this side of the Atlantic in the so-called carbolic acid treatment of Professor Lister." The main concept of Lister's work that the infection was introduced at the time of the operation had been overlooked. Nonetheless an increasing number of surgeons around the world had recognized the need to avoid wound contamination. Lister had made a major contribution to surgical progress.

Despite the introduction of gowns, masks, and rubber gloves, surgical infection continues to plague us. We have moved from carbolic acid sprays beyond the sulfonamides and penicillin to fourth-generation cephalosporins and other broad-spectrum antibiotics.

A few present day obstetricians and gynecologists (resident physicians in particular) do not appear to have the same fear of or respect for infection as did their predecessors and must be made to recognize that the basics for prevention of infection in the operating room have not changed in that after the surgeon has scrubbed, gowned, and gloved appropriately, the hands should not touch anything outside of the operating field, not even the gown. Meticulous hemostasis remains important as does gentle handling of tissues. The message that antibiotics are no substitute for good surgical technique must continue to be emphatically delivered.

Improved nutrition, the ability to provide parenteral nutrition, and the use of hyperbaric oxygen in a few cases have contributed significantly to survival in serious surgical infections.

The appearance of human immunodeficiency virus infection is having a major effect on today's midwives, obstetricians, and gynecologists who are delivering infants from or operating on these women. Because in many cases the human immunodeficiency virus status is unknown, adherence to good surgical principles, namely avoidance of injury in the operating room and use of universal precautions, must be stressed. We must increase our knowledge of this disease and with compassion continue to care for these unfortunate women.

Significant infections obviously also occur in early and late pregnancy and may be bacterial, viral, or protozoan. Rubella, herpes, and toxoplasmosis infections continue to alarm our patients and acquired immunodeficiency syndrome now complicates an increasingly large number of pregnancies.

In gynecology human papillomavirus and herpes infections are viewed with concern by our patients because of links to malignant disease of the cervix and absence of a specific curative medication. Paul McDonough[4] in a presidential address before this Association discussed the tremendous potential of deoxyribonucleic acid and ribonucleic acid analysis for identification of infecting organisms and determintion of antibiotic sensitivity as well as the effects of this new technology on the whole field of microbiology.

Among other advances that have occurred in recent years, health care of the postmenopausal woman has assumed a much more important role in gynecologic practice including efforts to prevent or minimize the effects of osteoporosis, hypertension, cardiovascular disease, and endocrinopathy. Exercise, weight control, and screening for gynecologic, breast, and bowel cancer should be an integral part of the package.

Great improvements have been made in management of the premature newborn and to a lesser extent in the control of premature labor. In genetics the picture changes almost on a day-to-day basis. New approaches in repair of recurrent genital prolapse, in the field of laser-laparoscopic surgery, and in management of infertility have been rewarding. These few examples serve only to emphasize the astounding advances that have occurred in our field of medicine in the past 25 to 50 years.

Technologic advances, however, appear to have been counterbalanced by an overall weakening in the doctor-patient relationship, increasing distrust of physicians by patients and their families, resentment of charges by physicians that reflect the increasing cost of running an office but are perceived as price gouging. Occurrence of real or perceived unethical conduct or of frank malpractice perpetrated by persons whom the profession apparently fails to discipline also add to the list of

reasons for patient dissatisfaction and adverse criticism by the media.

Personal observations and those of colleagues, as well as opinions expressed by many patients and their relatives, have convinced me that the single major factor that impairs the doctor-patient relationship today is none of the above, it is the failure to listen to our patients. Second is failure to adequately explain the diagnosis and the plan of management so that patients have a realistic expectation of outcome. This is a constantly recurring complaint. One must seriously question whether the art of the practice of medicine and the quality of care are being sacrificed by some colleagues at the altar of the economics of practice. The basis of sound clinical medicine in any of its fields is to obtain a detailed history. To accomplish this one must listen to the information the patient provides, then perform an appropriate physical examination. It becomes particularly important for a specialist in a limited field to avoid "blinker vision" in care of the patient, especially if we are truly to claim that we are primary care physicians for women.

I am disappointed, but have ceased to be surprised, when a patient informs me "I have never had such a detailed examination" or after a rectovaginal examination: "I have never had that done before." We must ask ourselves why is this occurring. Are we in medical schools failing to impart the appropriate information? The proper techniques are being taught, but perhaps they are not always used in large centers with a high patient volume and emphasis may be placed on a short history, similar to that in a busy office. Board rounds or chart rounds plus a visit to the computer for laboratory results has often replaced rounds at the bedside accompanied by the nurse caring for the patient. It may be that we are not sufficiently emphasizing personal patient contact.

We emphasize risk management, but residents receive little training in the economics of practice, including cost containment, and insufficient preparation to obtain maximum use of community resources. It is unfortunately true to state that in some programs residents do not care for private patients and undergo attitudinal reorientation on entering private practice. One of my mentors, Dr. James MacFarlane, affectionately known to the students as "Gentleman Jim" would have his students sit around a bedside and obtain a full history question by question with discussion of the relevance of each question and of a possible diagnosis, next perform a step-by-step appropriate physical examination, and finally discuss which laboratory tests would be of significance and should be ordered. The 2-hour learning experience was as exciting and interesting for the patient as for the student. It was a unique demonstration of the art and practice of medicine by a clinician par excellence, which left an indelible stamp on those fortunate enough to complete a clerkship on his wards.

Numerous excellent candidates are applying, but are we selecting the right persons as medical students and residents? Perhaps too much emphasis is placed on academic and financial ability in comparison to the patience, tolerance, and compassion needed to care for the young, the elderly, the sick and disabled, or of more importance the ability and willingness to communicate with patients from all levels of society.

One might assume that recruitment into obstetrics and gynecology would be difficult because of the malpractice problem. On the contrary, most good programs continue to have a large number of excellent applicants. Increasing numbers of women and minorities are entering our field of practice, but it still remains to be seen what attitudinal changes that will bring.

In the current climate in which we practice, an attitude of caring and concern by the physician and the ability to communicate with the patient and her family have a major effect on individual exposure to the risk of malpractice litigation.

As we stand on the threshold of a new decade, many of the problems that face us involve social rather than purely medical issues. Highlighted among those are teenage pregnancy, low birth weight and infant mortality, acquired immunodeficiency syndrome, substance abuse, domestic violence and child abuse, medical care for the poor and near poor, and care of the elderly, particularly those in whom mental or physical capability has deteriorated to the point they can no longer maintain their independence.

I recently had the privilege of serving on one of the American College of Obstetricians and Gynecologists new standing committees devoted to health care for underserved women. It was an illuminating, challenging, exciting, and somewhat disappointing experience. It was exciting to sit with a group of persons who were recognizing the problem for what it is and trying to deal with it on those terms. The disappointing aspect was that a not inconsiderable segment of college membership has been unwilling to participate for a variety of reasons. The committee recognized that in the search for solutions, government programs remain a critical component in the effort to care for the poor and that coordination between state, federal, and other programs is needed to obtain the maximum benefit. Physicians must become more knowledgeable with regard to health care public policy as well as to the legislative process. The college has prepared and made available a government relations handbook to help membership in this respect. To be successful the political process must be carried down to grass-roots levels.

Maternal complications, low birth weight, and infant

mortality are inexorably linked with lack of prenatal care. Young, single women who are either black or Hispanic are at particular risk in this respect. Cost effectiveness of prenatal care has been clearly demonstrated yet increasingly greater numbers of women are having difficulty obtaining care.

Provider availability has been affected by low reimbursement rates in Medicaid and state programs. The liability crisis has greatly reduced the number of obstetricians and almost eliminated family physician participation in many areas. Many perceive increased risk of a lawsuit if treating the poor; however, data provided to the committee did not offer statistical confirmation of that fact. Obstetricians and gynecologists will find it increasingly difficult to win public and legislative support for changes in remuneration or tort reform in the face of reluctance or even refusal to treat the poor, the pregnant poor, and the elderly.

Although offered as a solution, Medicaid has many disincentives built in for both the patient and the provider. Provision of the documentation demanded of many patients has been very difficult for a variety of reasons including lack of personal records, of know how, and of transportation. They become discouraged and disinterested. Women on presumptive eligibility drop out of the system before delivery, or eligibility is denied after care has started or even after delivery, which does little to promote participation by physicians. Provision of a full choice of family planning services for those families requesting it must be a priority item. Whereas opposed by some persons it is increasingly obvious that education with regard to reproductive physiology and disease transmission must become an integral part of the school curriculum by the time the student reaches puberty. One may debate the moral and religious aspects of such a policy, but delaying it until the senior highschool level makes absolutely no sense. Many of the young women we care for have had one or more children by the time they reach age 15 years. The concept of preconceptional counseling will remain a dream for years to come under the present system.

Medicaid for the younger and Medicare for the older patients plus a variety of local and state programs offer the only source of care for many. Another large group with a serious problem are those persons or families who have limited insurance or may have recently lost insurance because of a job change or can no longer afford the increasingly high premiums. In fact those in the "low middle income group" probably have greater difficulty obtaining health care than do the poor. They face financial disaster when serious illness occurs. In good conscience, can we allow this to continue?

To compound the whole issue it appears that insurance companies with increasing frequency are following the federal example to limit, dispute, and delay reimbursement to the provider or the patient. In addition, denial of applications for insurance has become more common, as has denial of a claim or even cancellation of insurance after a service has been rendered. Inability to obtain insurance is certainly not limited to lower income or poor women. The cost of private insurance is increasingly unaffordable when obtainable. The potential of serious illness or accident to bankrupt a family has never been higher.

Public pressures are again building for a national health system of some kind and it is obvious that the stage is set differently at this juncture in time. Medicare is in place and physicians are under increasing pressure to elect participating status. Medicaid has been and will continue to be expanded. Greater emphasis is being placed on expanding maternal-child health programs. A greater number of physicians are salaried than in the past. In addition to the reimbursement squeeze by the federal government and insurance companies, preferred provider, health maintenance organizations, and other forms of managed care are on the increase. Subtle rationing of care is occurring and will become more obvious.

Last January the *New England Journal of Medicine*[5] in its editorial[5] commented: "Now is the time for our profession to make common cause with the government and with the major private payers in seeking solutions to a pressing social problem that is not going to solve itself." If as reported 35 million Americans have no health coverage, it is impossible to deny that a serious problem exists and that a solution must be found. It is becoming increasingly important that associations such as the South Atlantic and our college insist on being heard in the dialogues surrounding the changes occurring in the health care system. We must avoid the ostrich approach adopted by many physicians in the United Kingdom before 1948 or history will again repeat itself. The problem is not going to disappear and changes in the way we provide care are inevitable. We must actively fight to retain our ability to provide high-quality care, yet extend its availability to all our citizens. We must strive to preserve independent decision making and personal choice for physicians and for patients. However, drastic problems require drastic solutions. Compromise will be needed on all sides. Private physicians will lose some of their independence, rates of remuneration will be held at lower levels and bureaucracy, which we already think is excessive, will increase if the system is not made "user friendly."

A new generation of excellent obstetricians and gynecologists including a higher percentage of women is entering the specialty and their needs and desires for a satisfying career are going to be quite different from ours.

The American College of Obstetricians and Gynecologists in a statement on "Access to Women's Health Care" in the newsletter in December 1988 called for availability of quality health care to meet every woman's need throughout her life, without costly delays or imposition of barriers. It further stated: "The college and its membership are committed to facilitating both access to and quality of women's health care. Fellows should exercise their responsibility to improve the health status of women and their offspring both in the traditional patient-physician relationship and by working within their community and at the state and national levels to assure access to high quality programs meeting the health care needs of all women."

The knowledge to provide such care is available, but is not presently reaching many of the women who need it most, for which we of the medical profession must bear some of the responsibility.

It is my hope that the political mists around health care will begin to clear and that in the 1990s each member of the South Atlantic Association of Obstetricians and Gynecologists will embrace the "access to care" statement and redouble his or her efforts to bring the concept to reality, although, I suspect that delivery will be preceded by a somewhat protracted and complicated labor.

Invasive carcinoma of the vulva

Changing trends in surgical management

Denis Cavanagh, MD, James V. Fiorica, MD, Mitchel S. Hoffman, MD, William S. Roberts, MD, S. C. Peter Bryson, MD, James P. LaPolla, MD, and Desmond P. J. Barton, MRCOG, FRCS(Ed)

Tampa, Florida

Four hundred fifteen patients who had invasive carcinoma of the vulva were treated with primary surgery from July 1, 1955, through June 30, 1989. Three hundred seventy-six (90%) of the patients had squamous carcinoma. Two hundred fourteen patients (52%) had radical vulvectomy with inguinofemoral lymphadenectomy. Twenty-four patients (6%) underwent radical vulvectomy with pelvic exenteration for advanced disease, and 55 patients (13%) had nonradical operations. The remaining 122 patients (29%) underwent radical vulvectomy, inguinofemoral lymphadenectomy, and pelvic lymphadenectomy. The primary morbidity was associated with lymphedema (8.6%) and groin wound breakdown (54%). No intraoperative deaths occurred among the 415 patients treated surgically, but there were 17 deaths (4%) within 28 days of operation. The absolute 5-year survival rate was 85% in patients with negative inguinofemoral lymph nodes and 39% when these lymph nodes were positive for metastatic carcinoma. The overall absolute 5-year survival rate was 67%. (AM J OBSTET GYNECOL 1990;163:1007-15.)

Key words: Invasive carcinoma of vulva, vulvectomy, inguinofemoral lymphadenectomy

Invasive carcinoma of the vulva is uncommon and accounts for only approximately 0.3% of all female cancer deaths.[1] However, the steady increase in life expectancy has brought carcinoma of the vulva into more importance among gynecologic malignancies. This is especially so in states with a large number of elderly citizens. In the state of Florida two thirds of patients with cancer are over 65 years of age, compared with approximately 50% in the nation as a whole. The 1980 census reported that Florida's population of approximately 10 million included 17.3% elderly, compared with 13% for the nation as a whole. By the year 2000 the percentage of elderly among the population is expected to increase nationwide, and Florida's population is estimated to be 15 million, with an estimated elderly population of 19.3% or almost 3 million people. With this futher increase in the elderly population the number of cancer cases is expected to almost double by the year 2000. Nationwide, it is estimated that carcinoma of the vulva accounts for 3% to 5% of all gynecologic malignancies, but on the Gynecologic Oncology Service at the University of South Florida in 1988, 30 of 304 patients with invasive gynecologic malignancy had carcinoma of the vulva (10%).

Just 40 years ago the absolute 5-year survival rate for carcinoma of the vulva was 15%.[2] However, a significant improvement in survival has occured because of earlier diagnosis and a better understanding of the nature and modes of spread of this disease.[2-15]

In the not too distant past patients with invasive carcinoma of the vulva were routinely treated with radical vulvectomy and bilateral inguinofemoral (groin) and pelvic lymphadenectomy; now this treatment mode has been seriously questioned.[16] Early vulvar carcinoma has been treated without bilateral groin node dissection for over a decade,[13] and exenteration has proved advantageous for prolonged survival in selected patients with advanced disease.[17] A better understanding of the nature of this cancer, especially the acceptance of the facts that the pelvic nodes are rarely primarily involved and that tumor embolization is the main mechanism for lymphatic spread, has led to changes in the basic operation.

These changing trends in the surgical management of invasive carcinoma of the vulva led us to review our experience over the 34-year period from July 1, 1955, through June 30, 1989. One surgeon (D. C.) participated actively in the management of most of these patients, and all were treated at the University of Miami (1955 to 1966), St. Louis University (1966 to 1977), and the University of South Florida in the

There is no drainage to the left groin nodes *(D)*. Bilateral lymphadenectomy was performed and all nodes were negative for metastatic tumor.

Tampa/St. Petersburg area (1977 to 1989). The therapeutic implications of the findings are discussed.

Patients and methods

Four hundred seventy-six patients were treated for invasive carcinoma of the vulva from July 1, 1955, through June 30, 1989. Of these, 415 patients had primary operation and had adequate data for evaluation. A retrospective analysis was conducted with regard to stage of disease according to the classification of the International Federation of Gynecology and Obstetrics, histopathologic diagnosis, and type of surgical treatment. The main goal of this analysis was to evaluate the effect of these factors on survival and morbidity patterns, and draw conclusions that could improve results in the management of this disease.

Preoperative investigations generally undertaken were as follows: (1) Routine studies included a complete blood count, urinalysis, biochemical profile, serologic testing, blood urea nitrogen, and 2-hour postprandial blood glucose; (2) a Papanicolaou smear was taken of the cervix, and colposcopy of the cervix and vagina was carried out as necessary. The toluidine blue test was used to identify high-risk areas and suspicious lesions were sampled. All outside slides of biopsy specimens were reviewed before operation. (3) Patients were screened for granulomatous disease of the vulva, with special attention recently to typing for the human papilloma virus. (4) Radiologic studies included x-ray films of the chest, intravenous urogram, and barium enema. Recently ultrasonography for liver metastasis and computed axial tomography for the assessment of pelvic and paraaortic lymph nodes have been used. In the past lymphography was routine but now it is only used in carefully selected cases because of the association with lymphangitis. More recently we have used lymphoscintigraphy. This study does not show whether nodes are positive or negative, but the drainage pattern of the lesion can be demonstrated with an intralesional injection of technetium 99 (Fig. 1). (5) Examinations under anesthesia, cystoscopy, and sigmoidoscopy were carried out as indicated. (6) Medical and anesthesiology consultations were obtained before operation.

During the period between 1955 and 1977 the standard operation for invasive carcinoma of the vulva was radical vulvectomy with bilateral inguinofemoral lymphadenectomy and pelvic lymphadenectomy. However, more recently we have discontinued the practice of routine bilateral pelvic lymphadenectomy. Even in patients with clitoral involvement, melanoma, or Bartholin's gland carcinoma, bilateral inguinofemoral lymphadenectomy with radical vulvectomy has become the standard approach.

When possible, two surgical teams were used to de-

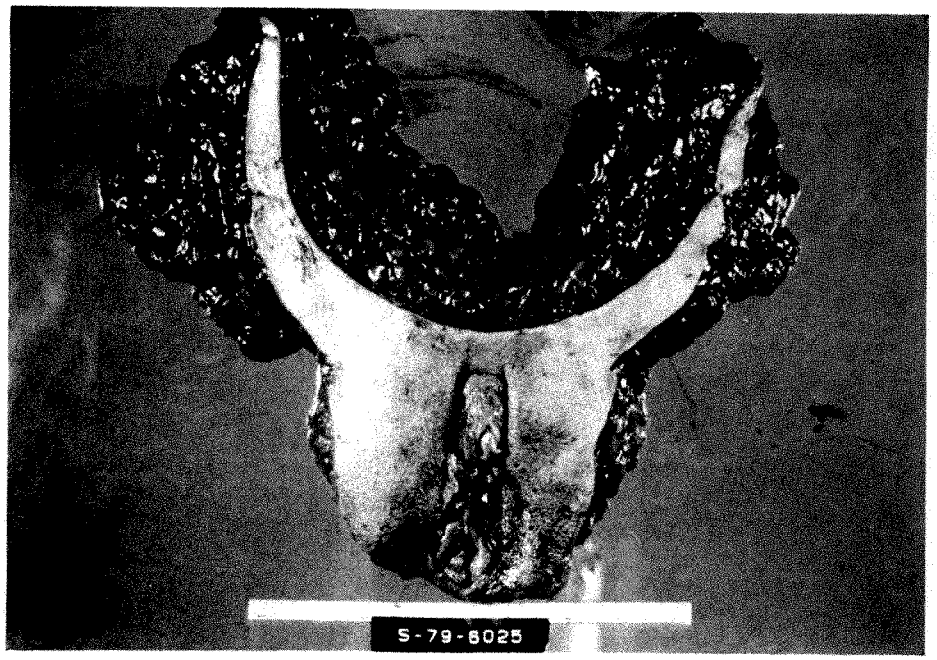

Fig. 2. Radical vulvectomy specimen with vulva removed in continuity with the inguinofemoral lymph nodes.

crease operating time. The procedure was begun with simultaneous bilateral inguinofemoral lymphadenectomy, and then proceeded to bilateral extraperitoneal lymphadenectomy, radical vulvectomy, or both. The operating time for the standard operation ranged from 90 to 270 minutes, with a mean of 150 minutes. With experience the technique has been modified over the years. During the early years an interspinous incision was made, the flaps were undercut, and the groin nodes removed. This resulted in wound breakdown in 90% of patients and therefore the technique was changed. For many years a "winged" incision was made to remove the skin over the inguinal nodes. The tips of the "wings" rested on the anterior superior iliac spines with the upper part of the incision being interspinous in location, and the lower part extending along the inguinal skin creases and into the labiocrural folds to clear all lesions by at least 2 cm. Removal of the lymph nodes was performed en bloc with the vulvar specimen so that continuity of the labiocrural lymphatics was maintained (Fig. 2). The mons pubis was removed and special attention was paid if the clitoris was involved. Dissection was carried down to the fascia so that all tissues were removed superficial to the urogenital diaphragm. Resection of the vagina, urethra, anus, or even bone was performed if the tumor involved these sites. In most patients a covering was placed over the femoral vessels by bilateral transposition of the sartorius muscles. More recently dura mater grafts have been used (Fig. 3).

In 1981 a significant modification in surgical technique occurred. This was based on the fact that lymphatic spread is primarily by embolization and that arrest of significant numbers of cancer cells in the labiocrural lymphatics is very unlikely. Three separate incisions are now used: one incision over each groin and the third is the vulvectomy incision. The groin incisions extended from the anterior superior iliac spine to the pubic tubercle bilaterally, with an elliptical portion of skin approximately 3 cm in maximum width removed from each groin together with the inguinofemoral lymph nodes. This technique leaves a small skin bridge between each area of groin node dissection and the vulva, thus allowing increased vascularity and better wound healing. These groin wounds are closed with no. 2 polypropylene retention sutures and staples. They are drained with Jackson-Pratt drains on low suction. The sutures and staples are left in position for at least 3 weeks (Fig. 4) and are removed in the outpatient clinic. Showers twice daily using a "shower-head" are allowed after 1 week to keep the groin and vulvar areas clean.

Postoperative follow-up has consisted of follow-up every 2 to 3 months for the first 2 years and thereafter at longer intervals, but not exceeding 6 months unless the patient was lost to follow-up. Specimens for vaginal cytologic examination were obtained at each visit. Chest radiographs, and more recently mammograms, have been obtained at yearly intervals with other investigations such as computed axial tomography, ultrasonography, bone scans, or magnetic resonance imaging studies only as indicated.

Adenocarcinoma	20 (5%)
Melanoma	19 (5%)
TOTAL	415

Results

Clinical picture. The ages of the patients ranged from 24 to 92 years (median age, 67 years). On review of the epidemiologic profile of these patients, the high-risk patient in our study was typically white, nulliparous, and weighed 70 kg. Pruritus vulvae was the main complaint in over 70% of the patients. Other notable coexistent problems were diabetes (12%), invasive cervical carcinoma (4%), and other cancers (3%). Two of the patients were pregnant when the diagnosis of carcinoma of the vulva was made.

Clinical stage. The clinical stage of the disease was assigned (Table I) in accordance with the International Federation of Gynaecology and Obstetrics Classification that was in effect until 1988, because the original data were not available to allow accurate staging according to the new surgical system. Thus some patients who had perineal involvement and were classified as having stage III disease would currently be classified as stage I or stage II, whereas some of the patients with stage I and stage II disease who had positive nodes would currently be classified as having stage III or stage IV disease.

Histopathologic results. The histopathologic distribution of the lesions is listed in Table II; 90% of the carcinomas of the vulva were of squamous cell type.

Types of surgical treatment. The types of surgical treatment are listed in Table III. All patients were treated according to the stage of disease rather than the histopathologic type of the lesion. The general state of health of the patient was also considered in the decision on the type of surgical treatment to be performed. Twenty-four of 415 patients (6%) underwent ultraradical procedures for advanced local disease. Of these, 18 patients had an anterior or posterior exenteration and six patients had a total pelvic exenteration. The general

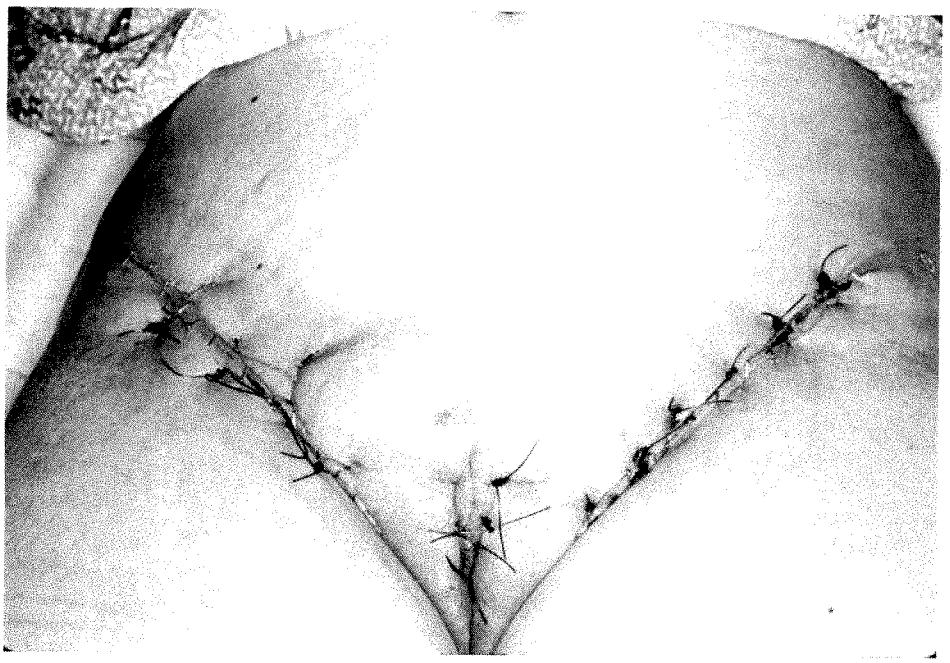

Fig. 4. Three-incision approach to radical vulvectomy and bilateral inguinofemoral node dissection, with closure using No. 2 polypropylene retention sutures and skin staples.

state of health correlated well with the age of the patients; whereas the median age at treatment was 67 years for the whole group, it was 44 years in the patients who had exenteration.

Mortality and morbidity. Although no intraoperative deaths occurred, 17 of the 415 patients (4%) died within 28 days of operation. Ten died of pulmonary embolism and four of myocardial infarction. One died of postoperative hemorrhage associated with pelvic lymphadenectomy. Postoperative osteomyelitis of the pubis with septic shock was the cause of death in one patient. In one patient the cause of death was unknown.

The morbidity pattern assessed in 360 patients is shown in Table IV. Groin wound breakdown occurred in 195 of 360 patients (54%). This was the primary cause of morbidity but was not difficult to treat. The wounds were irrigated with 50% hydrogen peroxide in saline solution three times daily and packed with honey-soaked dressings.[18] Skin grafting was necessary in only two patients. A femoral artery ruptured after operation in three patients and a femoral vein ruptured in two cases, but this complication was eliminated with the use of sartorius muscle transposition or dura mater allografts. Postoperative leg edema was common and persistent lymphedema was a significant problem in 31 of 360 patients (8.6%).

The overall 5-year survival is given by clinical stage of the disease in Table V. Data on 5-year survivals were limited, and no meaningful 10-year survival data were available. Of the 203 patients for whom an uncorrected 5-year survival rate was available, 67% were alive at 5 years. Eighty-six percent were alive if the carcinoma had been diagnosed in stage I, but only 36% of patients with stage IV disease were alive at 5 years. Because of the use of the clinical staging system before 1988, these data should be interpreted with caution when their application to the new surgical staging system is considered.

Table III. Invasive carcinoma of the vulva (1955-1989)—Distribution by surgical treatment

Surgical treatment	*No. of patients*
Radical vulvectomy with bilateral inguinofemoral lymphadenectomy	214 (52%)
Radical vulvectomy with bilateral inguinofemoral and pelvic lymphadenectomy	122 (29%)
Radical vulvectomy with bilateral inguinofemoral and pelvic lymphadenectomy and exenteration	24 (6%)
Total vulvectomy, partial vulvectomy, and other nonradical operations	55 (13%)
TOTAL	415

The absolute 5-year survival rate was 85% for patients with groin lymph nodes that were negative for metastatic carcinoma and 39% with positive groin lymph nodes (Table VI). Patients who survived 24

Table IV. Invasive carcinoma of the vulva (1955-1989)—Postoperative mortality and morbidity

	No. of patients
Mortality (N = 415) (to 28 days)	17 (4%)
Morbidity (N = 360)	
Groin wound breakdown	194 (54%)
Femoral vessel rupture	
Arterial	3 (0.8%)
Venous	2 (0.6%)
Chronic lymphedema	31 (8.6%)

Table V. Carcinoma of the vulva (1955-1984)—Absolute 5-year survival by clinical stage

Stage	*No. of patients*	*Survival*
I	88	76 (86%)
II	59	37 (63%)
III	42	19 (45%)
IV	14	5 (36%)
TOTAL	203	137 (67%)

months after the operation who had positive groin lymph nodes had a 5-year survival rate equal to those with negative lymph nodes. Of 122 patients who had a radical vulvectomy with bilateral groin and pelvic lymphadenectomy, none had positive pelvic nodes with negative groin nodes. Twenty-four of 122 patients (20%) had positive pelvic nodes; only 5 of these (20%) survived 5 years. None of the patients with positive common iliac nodes survived 5 years.

Recurrences—Management and results. A detailed recurrence analysis was performed on 80 patients with carcinoma of the vulva treated between 1977 and 1983. Twenty-three patients were excluded from analysis (7 postoperative deaths, 6 dead of intercurrent disease, 7 treated palliatively, 3 lost to follow-up). Of the 57 eligible patients, 19 (33%) had a recurrence of disease. The sites were vulva (9), groin (1), vulva and groin (1), pelvis (1), abdomen (1), spine (1), lung (3), and undetermined (2). Fourteen of these 19 patients (74%) died of disease. All five patients who survived 5 years had an isolated vulvar recurrence treated with wide local excision.

Perianal lesions—Management and results. From Jan. 1, 1985, through June 30, 1989, a detailed analysis was made of 89 patients who had radical vulvar operation for primary squamous cell carcinoma of the vulva. Thirty-two (36%) of the tumors involved the perianal or anal tissues. Twenty-five patients had stage III disease and seven patients had stage IV disease. Twenty-five of the 32 patients had radical excision of their tumors without colostomy. Two of the 25 excisions included resection of the majority of the anus, and both patients subsequently had severe fecal incontinence. In 12 patients the resection involved partial removal of the external anal sphincter, and persistent postoperative fecal incontinence developed in four of these patients. In the remaining 13 patients the resection involved partial removal of the anal skin, but the external anal sphincter was intact. One of these patients had postoperative fecal incontinence that was unchanged from her preoperative state. Thus carcinoma of the vulva involving perianal tissue can be resected in most cases with adequate preservation of external anal sphincter function. If the sphincter is damaged during operation, there is the potential for subsequent fecal incontinence.[19] In nine patients a portion of the external anal sphincter was excised during operation and the anus was reconstructed with the use of local cutaneous flaps.[20] Bilateral rhomboid flaps were used in seven patients, and two patients had advancement of local full-thickness skin flaps. All nine patients had a satisfactory anatomic result and were ultimately fecally continent. Of the 25 patients who underwent radical perianal excision, one was lost to follow-up, two died of disease at 6 months and 56 months (the two patients who underwent anectomy), and one patient experienced local recurrence at 22 months that was managed successfully with radiotherapy. The mean follow-up period was 23 months (range, 5 to 43 months).

Table VI. Carcinoma of the vulva—Absolute 5-year survival by inguinofemoral node status

Inguinofemoral node status	*No. of patients*	*Survival*
Negative	126	107 (85%)
Positive	77	30 (39%)
TOTAL	203	137 (67%)

Comment

There are ever-changing methods for treatment of carcinoma of the vulva, but radical operations have dramatically improved survival. However, because our aim is to treat the patient and not merely the disease, practitioners must analyze past mistakes and improve patient care. Recently the trend has been toward less radical surgical procedures. Some authors suggest treatment of superficially invasive or "microinvasive" carcinoma of the vulva with wide local excision and ipsilateral and even superficial inguinal lymphadenectomy.[13, 21, 22] One problem with performing superficial inguinal lymphadenectomy is that at least three cases have been reported to have positive deep femoral nodes in the presence of negative superficial nodes.[23-25] An-

other problem is that "microinvasive" carcinoma of the vulva has not been satisfactorily defined. In fact, the Subcommittee on Microinvasive Cancer of the Vulva of the International Society for the Study of Vulvar Disease recommended that the term be abandoned.[26] "Superficial invasion" is a better term, and much thought has been given to its definition.[27, 28] However, when the term "superficially invasive" was used to describe vulvar cancers up to 5 mm in thickness, Sedlis et al.[29] reported that 57 of 272 patients (21%) had metastasis to one node and 28 of 272 (10.3%) had two or more lymph nodes positive for metastatic disease. To clarify the situation the Gynecologic Oncology Group has designed a prospective study to evaluate the management of early invasive carcinoma by wide excision and ipsilateral groin lymphadenectomy. Currently, conservative approaches merit utilization when poor-risk patients are involved. However, like Sedlis et al.,[29] we are not convinced of the validity of abandoning the standard operation at this time in patients with "superficially invasive" disease up to 5 mm, unless other low-risk criteria such as stage I disease, lateral site of the primary lesion, grade 1 tumor, and no lymph or vascular space permeation are taken into consideration. Obviously most of this information is not available before definitive operation.

Lymphangiography can be used to identify lymph node metastasis, but has a limited application in carcinoma of the vulva because it predisposes the patient to lymphangitis and lymphedema. Lymphoscintigraphy has been used to detect nodal location in breast cancer,[30] and recently we have used it in cases of vulvar carcinoma to identify the drainage pattern for individual lesions. It is too early to assess the value of this diagnostic tool in cancer of the vulva at this time.

In 1986 Homesley et al.,[31] in a randomized study of 114 patients, reported that radiotherapy to the groin nodes and pelvis provided a better survival rate than pelvic lymphadenectomy in patients with two or more positive inguinofemoral lymph nodes. Thus radiotherapy now has a place as an adjunct to radical vulvectomy and bilateral groin lymphadenectomy in selected patients.

In 1989 Thomas et al.[32] reported success with the use of concurrent radiation and chemotherapy in selected patients with vulvar carcinoma. We have used this approach in patients with advanced nonresectable disease, and we believe that currently this approach should be reserved for such cases and patients with combined distal and local recurrences. As we found in our patients, vulvar recurrence can be successfully treated with wide excision, but with distant recurrence the prognosis is very poor.

Despite the above-mentioned "innovative methods" for treatment of invasive carcinoma of the vulva, the standard curative treatment remains radical vulvectomy and bilateral groin lymphadenectomy. This remains the treatment of choice even for patients with melanoma of the vulva,[33] and we treated 19 such patients in this manner. However, in our hands the results are not as good as for squamous carcinoma, and of 10 patients followed up for 5 years in this series only 3 were alive and free of disease. Because all the recurrences were associated with metastatic disease, the performance of bilateral groin dissections in patients with no palpable nodes may not be indicated.

The absolute 5-year survival rate in our patients was 85% in cases with negative lymph nodes and 39% in patients with positive lymph nodes, for an overall uncorrected 5-year survival rate of 67%. With a median age of 67 years, on the basis of appropriate life-table data, life expectancy without cancer of the vulva, matched for age and sex is approximately 80% for 5 years. Considering the older median age of our patients, our results (from 1955 to 1984) are similar to those obtained by others in recent years.[34]

A prominent problem in our series was delay in diagnosis; one third of the patients had stage III or stage IV disease at diagnosis. Many of the patients we studied should have undergone a biopsy procedure sooner, and there was apparent need for physician and patient education.

Groin wound breakdown was the main source of postoperative morbidity in the patients studied. As suggested by Hacker et al.,[35] we have used the three-incision approach over the past 8 years. This technique has reduced the groin breakdown rate from 70% to less than 20%. There have been no recurrences in the skin bridge to date in our series, but one case has recently been reported,[36] and thus we will continue to examine our patients every 2 to 3 months for the first

2 years after operation. However, it should be pointed out that the recurrence reported by Schulz and Penalver[36] was associated with a separate vertical groin incision; perhaps the separate oblique groin incisions will afford more protection from recurrence.

Another significant problem with the standard operation is persistent lymphedema of the legs that occurred in nearly 9% of our patients. Because operative treatment of lymphedema is unsatisfactory at this time, management consists of elevation of the legs and the prompt antibiotic treatment of cellulitis. Within 2 years collateral lymphatic pathways usually become established, and the condition may improve if infection is controlled.

Sexual dysfunction is common after radical vulvectomy, and there are few studies on this subject.[7, 37, 38] Although the capacity for intercourse usually remains, patients experience a sense of disfigurement and a reduction in genital sensitivity. Some patients remain orgasmic after vulvectomy, but in one study 70% to 80% reported the end of sexual activity.[7] In evaluating this factor, however, it should be kept in mind that in most series the patients are in the seventh decade of life when they have invasive disease. Modifications in the operation have been proposed to reduce sexual dysfunction, and in recent years we have tried to spare the anterior vulva, mons, and especially the clitoris unless these areas are within 3 cm of the invasive lesion. Dyspareunia and even retention of urine may occur as a result of vaginal stenosis, but this problem is readily treatable by perineotomy and transverse closure of the incision. Skin flaps to replace vulvar tissue are often helpful in enlarging the introitus, and the patient should be encouraged to use a vaginal dilator and resume intercourse after operation.

In our opinion, the preferred mode of treatment for most patients with invasive carcinoma of the vulva is radical vulvectomy and bilateral groin node dissection. There are certain patients who would benefit from alternative therapies, such as bilateral inguinofemoral lymphadenectomy and subtotal vulvectomy with clitoral sparing for posterior lesions.

Exenterations may help patients with locally advanced carcinoma of the vulva, and a recent review of the literature reveals 42 of 94 patients (45%) who survived for 5 years[17, 39-45] (Table VII). However, Boronow et al.[46] have reported good results in the treatment of advanced vulvar disease with initial radiation to reduce or eliminate the need for exenterative surgery. Thus in different centers the approach to the problem of advanced vulvar cancer is handled in different ways, each with a margin of success. The basic problem in evaluation of these treatment methods is that no center has enough advanced cases to conduct a controlled randomized study.

In summary, modifications in surgical technique have reduced the most common complications associated with radical vulvectomy and bilateral groin node dissection. However, because recurrence is the most serious posttreatment problem in patients with cancer, improvement in survival rates is a continuing goal. Earlier diagnosis and prompt referral for appropriate treatment are critical elements for success in this disease, and thus improved patient and professional education is vital.

Bacterial vaginosis and trichomoniasis vaginitis are risk factors for cuff cellulitis after abdominal hysterectomy

David E. Soper, MD, Richard C. Bump, MD, and W. Glenn Hurt, MD
Richmond, Virginia

To assess the relationship between either bacterial vaginosis or trichomoniasis vaginitis and posthysterectomy infection, preoperative evaluation of the vaginal secretions was performed in 161 women undergoing abdominal hysterectomy. Thirty-two patients (19.9%) and 27 patients (16.8%), respectively, met the diagnostic criteria for bacterial vaginosis and trichomoniasis vaginitis. Patients with either bacterial vaginosis or trichomoniasis vaginitis were more likely than control subjects to have cuff cellulitis, cuff abscess, or both (relative risk 3.2, 95% confidence interval 1.5 to 6.7 for bacterial vaginosis; relative risk 3.4, 95% confidence interval 1.6 to 7.1 for trichomoniasis vaginitis). Preoperative vaginitis had no effect with respect to the incidence of postoperative wound infection, urinary tract infection, or intravenous line phlebitis. *Bacteroides* sp., *Peptostreptococcus* sp., and/or *Gardnerella vaginalis* ("bacterial vaginosis organisms") were isolated from the vaginal cuff in the majority of patients with postoperative cuff cellulitis. Bacterial vaginosis and trichomoniasis vaginitis are risk factors for the development of posthysterectomy cuff cellulitis. (AM J OBSTET GYNECOL 1990;163:1016-23.)

Key words: Bacterial vaginosis, trichomoniasis, cuff cellulitis

Pelvic cellulitis remains the most common serious infectious complication after abdominal hysterectomy.[1] Postoperative cuff cellulitis, pelvic abscess, or both occur in up to 18% of women not receiving antibiotic prophylaxis.[2] The pathogenesis of this infection involves the invasion of spaces superior and lateral to the vaginal cuff, including the parametrial tissue, by endogenous microorganisms found in the vagina.

Bacterial vaginosis is associated with an alteration of vaginal bacterial flora as evidenced by a significant increase in the concentration of *Gardnerella vaginalis* and anaerobes in the vaginal fluid.[3] Patients with vaginal trichomoniasis have similar changes in vaginal flora.[4] Several investigators[5, 6] have demonstrated that potentially pathogenic bacteria persist in the vagina despite the use of a povidone-iodine preparation. Infection after surgical entry into the vagina during abdominal hysterectomy is a direct result of the residual bacterial inoculum in the vagina. It follows that those disorders associated with increased concentrations of vaginal microorganisms, such as bacterial vaginosis and vaginal trichomoniasis, may increase the risk of postoperative cuff cellulitis and possibly wound infection. We designed the following prospective study to address this issue.

Material and methods

Study population. From April 15, 1987, through Jan. 15, 1989, a total of 161 consecutive qualifying patients undergoing abdominal hysterectomy on the Gynecology Service at the Medical College of Virginia Hospitals were included in the study. The study was approved by the Committee for the Conduct of Human Research and each subject gave consent. Patients were excluded if they had received antibiotics within the preceding 2 weeks or if they required cardiac antibiotic prophylaxis. Also excluded were patients undergoing hysterectomy on the Gynecologic Oncology service or patients who had their hysterectomies performed by or under the supervision of gynecologists other than the three coauthors of this article. All operations were performed by gynecologic residents with the assistance of one of the three coauthors.

None of the patients in the study received antibiotic prophylaxis. No preoperative douching was performed. Preoperative vaginal, perineal, and abdominal scrub with povidone-iodine was used in all patients. The surgical technique was standardized. No drains were used with the exception of a subfascial Jackson-Pratt drain in patients having a Maylard incision. The vaginal cuff was closed in all patients. A Foley catheter was left in place until the morning of the first postoperative day.

Clinical evaluation. Immediately before the operation, after the induction of anesthesia but before the vaginal scrub, the vagina was evaluated by one of the coauthors. The consistency of the vaginal secretions was recorded and a pH was determined with colorpHast indicator sticks (MC/B Manufacturing Chemists, Inc.,

Cincinnati) with a range from 4 to 6.5. The lateral vaginal walls were swabbed with a cotton-tipped applicator, which was mixed with two drops of physiologic saline solution on a glass slide. A second slide was prepared with 10% potassium hydroxide and was immediately evaluated for the presence of a fishy aminelike odor (whiff test). Both slides were entirely examined at ×400 with a light microscope. Clue cells were identified as vaginal epithelial cells with such a heavy coating of bacteria that the peripheral borders were obscured. The percentage of epithelial cells represented as clue cells was calculated after evaluation of a minimum of four representative fields. Trichomonads were identified as motile flagellated organisms slightly larger than white blood cells. The potassium hydroxide wet mount was examined for the presence of hyphae.

Microbiologic studies. Cultures of the endocervix were performed for *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Cervical specimens for *N. gonorrhoeae* were inoculated onto Transgrow media (Carr-Scarborough Microbiologicals, Atlanta) and incubated in 5% carbon dioxide at 37° C. Oxidase-positive colonies were presumptively identified as *N. gonorrhoeae* by Gram stain showing gram-negative diplococci. Cervical specimens for *C. trachomatis* were extracted into a sucrose-phosphate-glutamate transport medium. Specimens were then inoculated and centrifuged onto coverslips with cycloheximide-treated McCoy cells in two vials. After incubation in 5% carbon dioxide at 37° C for 48 hours, the coverslips were removed and the cells were fixed in methanol and stained with a fluorescein-conjugated monoclonal antibody (MicroTrak, Syva, Palo Alto). Specimens were reported as positive when one or more fluorescing inclusion bodies were seen. A second pass was performed on the second vial of all negative specimens.

Definitions. A patient met the criteria for the diagnosis of bacterial vaginosis if she had ≥20% clue cells, no motile trichomonads, and two of three of the following criteria: pH ≥ 4.7, homogeneous discharge, and/or positive whiff test. A patient with a positive wet mount of the vaginal secretions for motile trichomonads was considered to have trichomoniasis. Control patients had <20% clue cells and no motile trichomonads on wet mount of the vaginal secretions.

Postoperative infections

Cuff cellulitis. Cuff cellulitis was diagnosed in patients with persistent fever (>100.4° F) on two occasions, excluding the first 48 hours postoperatively, in association with increased vaginal cuff tenderness and induration on bimanual pelvic examination.

Cuff abscess. A cuff abscess was diagnosed in patients with the criteria for cuff cellulitis who also had a palpable fluctuant mass located superior to the vagina. In all cases of cuff abscess, dilation of the cuff led to demonstrable drainage of purulent material.

Abdominal wound infection. A wound infection was diagnosed when a wound drained purulent material or serous fluid from which potential pathogens were recovered when cultured. Tissue induration, warmth, erythema, and increasing tenderness were also present.

Urinary tract infection. A urinary tract infection was diagnosed in patients with urinary symptomatology (i.e., urgency, frequency, and/or dysuria) in whom a catheterized urine culture grew $\geq 10^2$ colonies per milliliter of a single uropathogen. Urinary tract infection was also diagnosed in patients with persistent fever (>48 hours postoperatively) in whom no other source of fever could be found and in whom a catheterized urine culture grew $\geq 10^5$ colonies per milliliter of a single uropathogen.

Statistical analysis. Discrete data were tested for significance by means of the χ^2 test or Fisher's exact test. Continuous data were tested for significance with a two-tailed t test. All p values are based on two-tailed tests with $p < 0.05$ being considered significant. To determine the potential confounding effect of multiple variables, a multiple logistic regression analysis was performed. Variables that could be considered risk factors for infection after hysterectomy were included in both univariate and logistic regression analyses. These variables included the presence of bacterial vaginosis or trichomoniasis vaginitis, age, menopausal status, being a clinic patient, weight, preoperative serum albumin level, preoperative and postoperative hemoglobin levels, estimated blood loss, and operating time. Only those variables in the first regression with p values of <0.20 and age, because of a $p = 0.03$ in the univariate analysis, were included in the final regression model to avoid overparameterization of the model. Continuous variables used in the logistic analyses were median centered.

Results

Patient populations and perioperative data. The demographic characteristics of the study groups are shown in Table I. Only the younger age of the patients in the bacterial vaginosis group was significant when data were compared among the three groups.

The mean weights, preoperative and postoperative hemoglobin levels, serum albumin level, surgical procedure, duration of operation, and estimated blood loss are shown in Table II. There were no significant differences among the three groups when these parameters were compared.

Thirty-two patients (19.9%) met the diagnostic criteria for bacterial vaginosis and 27 patients (16.8%) met the criteria for trichomoniasis vaginitis. Eleven of the 27 patients (40.7%) with trichomoniasis vaginitis had evidence of concurrent bacterial vaginosis as previously defined. For this reason additional analyses were per-

formed. Patients with trichomoniasis vaginitis and concurrent bacterial vaginosis were combined with the group with bacterial vaginosis ($n = 43$), and patients with pure trichomoniasis vaginitis without concurrent bacterial vaginosis were separated into another group ($n = 16$). Fungal elements were seen on the potassium hydroxide preparation in only three patients.

A single patient had a positive culture for *Neisseria gonorrhoeae*. This patient was one of the control patients and had an uncomplicated postoperative course. Three patients—one in each group—had a culture that was positive for *Chlamydia trachomatis*. The chlamydia-positive patient in the group with trichomoniasis vaginitis had postoperative cuff cellulitis.

Postoperative outcome. Cuff cellulitis, cuff abscess, or both occurred in 32 of the 161 patients (19.3%). Patients with bacterial vaginosis were more likely to have cuff cellulitis, abscess, or both (relative risk 3.2, 95% confidence interval 1.5 to 6.7) than control patients ($p = 0.005$). The fever index was significantly higher in patients with bacterial vaginosis than in the control patients. Patients with trichomoniasis vaginitis were also more likely than control patients to have cuff cellulitis (relative risk 3.4, 95% confidence interval 1.6 to 7.1; $p = 0.002$) and had a significantly higher fever index. These data are summarized in Table III. In addition, four of six patients with cuff abscesses had preoperative bacterial vaginosis. Although the numbers are small, this difference was significantly different from the control group ($p = 0.03$).

The significant association of bacterial vaginosis with postoperative cuff cellulitis was even more evident when patients with trichomoniasis vaginitis and concurrent bacterial vaginosis were added to the group with bacterial vaginosis (relative risk 3.6, 95% confidence interval 1.8 to 7.1). When the patients with concurrent bacterial vaginosis were excuded from the group with trichomoniasis vaginitis, the number of patients became too small to result in any meaningful conclusion. Patients with pure trichomoniasis vaginitis did show an increased risk for development of cuff cellulitis; however, this risk failed to reach statistical significance (relative risk 2.3, 95% confidence interval 0.8 to 6.4; $p = 0.12$).

No significant differences were noted among groups with respect to the incidence of wound infection, uri-

nary tract infection, and intravenous line phlebitis. Bacterial vaginosis, trichomoniasis vaginitis, or both did not predispose to wound infection.

Analysis of risk factors. Only younger age was statistically significant in the univariate analysis of potential risk factors for cuff cellulitis (Table IV). Multiple logistic regression analysis identified three risk factors that were independently and significantly associated with the development of cuff cellulitis. These factors were bacterial vaginosis, trichomoniasis vaginitis, and a lower postoperative hemoglobin level. A higher preoperative hemoglobin level, younger age, and being a private patient all had an effect on the incidence of cuff cellulitis but failed to reach statistical significance (Table V).

All potentially confounding variables used in the logistic regression model were equally distributed among the three groups of patients with the exception of age (patients with bacterial vaginosis were younger than control patients). However, the independent relationship between bacterial vaginosis and cuff cellulitis was stronger ($p = 0.002$) than the relationship between age ($p = 0.08$) and cuff cellulitis (Table V). The number of private patients in the study was small ($n = 26$). This reflects the mix of clinic and private patients seen in the Benign Gynecology Service at the Medical College of Virginia and not the exclusion of private patients from the study. Despite the fact that 78% (25/32) of all cases of cuff cellulitis were diagnosed in clinic patients, 26.9% (7/26) of private patients, compared with 18.5% (25/135) of clinic patients, had cuff cellulitis (p = NS by univariate analysis, χ^2).

Consequences of morbidity. Patients with cuff cellulitis had a significantly longer duration of hospitalization when compared with their noninfected counterparts (8.1 ± 3.2 vs 5.1 ± 1.1 days; $p = 0.0001$). Also the fever index of patients with cuff cellulitis was significantly higher than it was for noninfected patients (207 ± 99.4 vs 75.2 ± 51.1 degree hours; $p = 0.0001$). This increase in the fever index carried over into the groups of patients with either bacterial vaginosis or trichomoniasis vaginitis; there was a significant difference in the fever index between both the groups with bacterial vaginosis and trichomoniasis vaginitis when compared with the control group (Table III).

Microbiology of postoperative infection. Cultures of the vaginal cuff from patients with postoperative cuff cellulitis were available in 29 of 32 patients (90.6%). These cultures reflect the polymicrobial nature of this infection. More than one organism was isolated from 27 of 29 patients (93%). More important, bacterial vaginosis organisms (*G. vaginalis, Bacteroides* sp., or *Peptostreptococcus* sp.) were isolated from 18 of 29 patients (63%).

Table V. Logistic regression analysis of risk factors for the development of postoperative cuff cellulitis

Characteristic	*Estimate*	*Standard error*	χ^2	*p Value*
Bacterial vaginitis	1.6928	0.5372	9.93	0.002

Clinic patient	−0.8440	0.5683	2.21	0.137

Comment

Risk factors for infection after hysterectomy have only been prospectively studied by Shapiro et al.[7] They found that the duration of the operation, lack of antibiotic prophylaxis, younger age, being a clinic patient, and an abdominal approach were significantly associated with infection at the operative site. All of our patients underwent abdominal hysterectomy and none received antibiotic prophylaxis. Results of our study failed to confirm that the duration of the operation, younger age, and being a clinic patient are significant risk factors for postoperative infection. In our study all surgery was performed in a standardized fashion by residents with direct assistance and supervision by one of the three coauthors. For this reason the duration of the operation may not be an indicator of surgical proficiency when compared with a study in which experienced private physicians are compared with residents in training. Younger age did have an effect on the incidence of cuff cellulitis, but this relationship failed to reach statistical significance (odds ratio 1.0, 95% confidence interval 0.9 to 1.0; $p = 0.08$). Moreover, the risk factors of younger age and being a clinic patient may have been indications of a patient's risk for bacterial vaginosis or trichomoniasis vaginitis rather than any inherent risk of infection. Our data suggest that this was indeed the case. Our analysis actually shows a trend toward the private patient being at increased risk for cuff cellulitis (Table V). This may well be related to the higher incidence of preoperative bacterial vaginosis in our private patients (23.1%) when compared with our clinic patients (19.3%).

Hemsell et al.[2] used a stepwise discriminant analysis to identify three factors (age, absence of excessive uterine bleeding, and absence of an abnormal uterus at bimanual examination) associated with postoperative infection. However, this report neither described the variables that were used in developing the model nor defined the risk factors. No one has previously evaluated the effect of preoperative vaginitis on the incidence of postoperative infection.

A number of infections occurring in women have been found to be associated with bacterial vaginosis. These infections include pelvic inflammatory disease,[5] postpartum endometritis,[8] and intraamniotic infection.[9] In addition, adverse pregnancy outcomes such as premature labor and preterm delivery have also been linked to bacterial vaginosis.[10, 11] In all patients it was thought that the increased concentrations of microorganisms in the vagina that are associated with bacterial vaginosis predisposed patients to an ascending infection.

Our data show that both bacterial vaginosis and trichomoniasis vaginitis are risk factors for the development of postoperative cuff cellulitis. We believe that the increased concentration of anaerobic bacteria, particularly *Bacteroides* sp. and *Peptostreptococcus* sp., in the vaginas of patients with bacterial vaginosis predisposes them to infection. This is supported by the fact that bacterial vaginosis organisms were isolated from the vaginal cuff of more than 60% of our cases of cuff cellulitis. The vaginal flora associated with trichomoniasis vaginitis is similar to that of bacterial vaginosis.[6] Moreover, trichomoniasis vaginitis is commonly associated with bacterial vaginosis. Whether this association is truly a reflection of two separate disorders or the result of the effect of the trichomonads themselves, causing an increase in vaginal pH and therefore enhancing bacterial adherence leading to the formation of clue cells, is unknown. In our study 40.7% (11/27) of patients with motile trichomonads also showed evidence of bacterial vaginosis (≥20% clue cells, pH ≥4.7, and/or a homogeneous discharge or positive whiff test). Additional analyses showed a weaker association between trichomoniasis vaginitis and postoperative cuff cellulitis when patients with concomitant bacterial vaginosis were excluded. However, it is important to consider trichomoniasis vaginitis as a risk factor for postoperative infection because of its association with bacterial vaginosis and because it is sometimes more easily recognized and diagnosed than bacterial vaginosis.

Logistic regression analysis also identified a lower postoperative hemoglobin level as a risk factor for cuff cellulitis. Univariate analysis of patients with and without cuff cellulitis, as well as analysis among study groups, failed to confirm this significance. Estimated blood loss was not a risk factor for infection. Low postoperative hemoglobin levels may be an indication of postoperative oozing and the resulting subclinical hematoma formation at the operative site, which may pre-

dispose to infection. However, only two of our patients with postoperative cuff cellulitis had clinical evidence of a postoperative hematoma. The statistical significance may not be clinically relevant in this instance.

Preventive strategies have primarily embraced the use of prophylactic antibiotics with variable preventive effects.[1,2] In our study more than two thirds of the cuff cellulitis occurring in the groups with vaginitis could be attributed to bacterial vaginosis, trichomoniasis vaginitis, or both (attributable risk 68.6% and 70.8%, respectively). Future studies should address the effectiveness of preoperative therapy of bacterial vaginosis and trichomoniasis vaginitis with regard to subsequent infection rates. In addition, the effect of perioperative prophylactic antibiotics with respect to risk reduction in patients with bacterial vaginosis or trichomoniasis vaginitis should also be assessed.

The morbidity associated with major postoperative infection is significant. In this study patients with postoperative cuff cellulitis remained in the hospital an average of 3 days longer than patients without the infection. Also the mean fever index of infected patients was more than double that of the uninfected patients. These data clearly support our contention that bacterial vaginosis and trichomoniasis vaginitis do not just predispose to "febrile morbidity" but to clearly diagnosed pelvic infection. Indeed 18.7% (6/32) of patients with cuff cellulitis had clear-cut cuff abscesses.

In summary, we have performed a prospective study to determine the effect of preoperative vaginitis on postoperative infectious morbidity after hysterectomy. Bacterial vaginosis and trichomoniasis vaginitis are risk factors for postoperative cuff cellulitis. Further study is needed to determine what modulating effects either preoperative therapy or perioperative prophylactic antibiotics have on these risk factors.

Editors' note. This manuscript was revised after these discussions were presented.

Discussion

DR. BERTRAM C. FINCH III, Charleston, South Carolina (Official Guest). The entity bacterial vaginosis has gotten much attention recently. After World War II, results of the first meaningful studies on "nonspecific" vaginitis were reported. In October 1954, Gardner and Dukes[1] incriminated a gram-negative pleomorphic rod as the single causative agent in the infection; they assigned the newly isolated bacillus the name *Haemophilus vaginalis.*[1] This organism has now been reclassified as the only member of a new genus, *Gardnerella.*[2]

G. vaginalis is found in 95% of symptomatic women with bacterial vaginosis and in concentrations 100-fold those of asymptomatic women with no signs of vaginitis or vaginosis. Nonetheless, the organism is found in the normal vaginal pool of up to 40% of asymptomatic women. Compared with these asymptomatic women, those with bacterial vaginosis also have a dramatic 1000-fold increase in total anaerobic bacteria.[3]

Bacterial vaginosis, defined by the same criteria as presented by Dr. Soper, has been recognized in more asymptomatic than symptomatic women. Bacterial vaginosis is said to be the cause of one third to one half of all infectious vaginal conditions and is symptomatically present in 12% to 19% of gynecologic patients.[3] In the past decade bacterial vaginosis has been significantly related to an array of obstetric and gynecologic morbidity; included in the list are premature labor,[4] premature rupture of the fetal membranes,[5] premature birth,[6] postpartum endometritis,[7] chorioamnionitis,[8] infection of the amniotic fluid,[4] pelvic inflammatory disease,[8] and now posthysterectomy cuff cellulitis and formation of cuff abscess.

Three diagnostic methodologies prevail: clinical, microbiologic, and Gram stain. Dr. Soper has used a meaningful clinical diagnosis of bacterial vaginosis that has been used by several authors; according to this definition bacterial vaginosis can be accurately diagnosed when three of four criteria are present. Gram stain appears to be the most sensitive diagnostic method[8]; it can be nonbiased, it lends itself to mass screening, and it allows late and repetitive analyses. Would this test detect other women with bacterial vaginosis who are thus at risk for postoperative morbidity?

Dr. Soper demonstrated that both bacterial vaginosis

and trichomoniasis vaginitis are risk factors for the development of postoperative morbidity, including fever index, prolonged hospitalization, and formation of vaginal cuff abscess. In fact 20% of those with cuff cellulitis also had an abscess. Would this frequent and more serious complication alone account for the increased fever index and prolonged hospitalization?

No intervention strategies were mentioned. Were the 32 women with cuff cellulitis treated with antibiotics? After discharge from the hospital, were any patients readmitted or later found to have conditions requiring antibiotic therapy?

Intraoperatively were any patients found to have pyosalpingitis or chronic pelvic inflammatory conditions that might increase their chances of postoperative fever, tenderness, and/or induration?

Dr. Soper mentioned the persistence of potentially pathogenic bacteria after the use of a povidone-iodine preparation. Indeed Monif et al.[9] showed a dramatic and rapid decrease in the number of aerobic and anaerobic bacteria in the vagina after its use. The effect lasted approximately 1 hour after the solution was used; changing the vehicle to polyethylene glycol (i.e., Betadine vaginal gel) prolonged the effect over a 3-hour period. Since these hysterectomies varied in length from just over 1 1/2 hours to just under 3 1/2 hours, averaging less than 2 1/2 hours, we wonder if the addition of Betadine vaginal gel to the "routine preparation" would reduce the postoperative infectious morbidity.

As Dr. Soper has indicated, as such data accrues, the pathophysiologic mechanisms for these associations will lead to appropriate prophylactic measures, preventive measures, or both. This article offers great potential for reducing infectious morbidity and may aid in controlling hospital expenses with a simple preoperative evaluation. As Gardner and Dukes[1] stated, "Perhaps most serious postoperative infections could be avoided if pelvic surgeons would perform just two simple tests: vaginal pH and a saline wet mount."

Dr. Guy I. Benrubi, Jacksonville, Florida. We are doing Gram stains because we are finding that what even experienced examiners think is bacterial vaginosis on wet preparations turns out not to correlate with what we are finding on Gram stain. Another interesting finding is that some people with bacterial vaginosis have *Mobiluncus* and some people with BV have *Gardnerella.* We have been doing some quantitative *Gardnerella* cultures. I wonder if that was considered at all. I also wonder whether *Mobiluncus* and *Gardnerella* play different roles in postoperative cuff cellulitis.

We also performed a study several years ago in which 2 gm of metronidazole was given by mouth the night before. We had a population very similar to that of Dr. Soper; 90% of our patients were from a clinic population. The postoperative infection rate, is 18% why not obtain the data while the patient is asleep and then begin treatment with some preoperative antibiotic that covers anaerobic bacteria. This study needed to be done, and I think we are well on our way in trying to elucidate this problem.

Dr. Karen Kreutner, Charleston, South Carolina. This topic was discussed at a full-day seminar at the annual meeting of the Infectious Disease Society. It is very controversial and there is a lot to be learned about BV. One of the main points is that the definition is not as presented in this article. It is very important that we define our terms according to the national standards, which do not, for example, include >20% clue cells, or we are going to end up with a great deal of confusion in the literature. We do not yet know how to treat bacterial vaginosis. *Mobiluncus* does play a role. *Gardnerella* can be downgraded in a number of patients. The newer methods of therapy seem to involve the use of intravaginal clindamycin. We just need to be careful to follow the standards if we are going to publish data.

Dr. William E. Josey, Atlanta, Georgia. I commend Dr. Soper for including trichomoniasis, because up to now most of the studies on infectious morbidity of this type have emphasized *Gardnerella*-associated vaginitis and have not said much about trichomoniasis. I think this is because the anaerobic overgrowth in both of these infectious vaginitides is very similar.

Dr. Soper (Closing). I too was involved in the Infectious Disease Society symposium, and there is no real gold standard for the diagnosis of bacterial vaginosis. Whether composite clinical criteria are used, which are what we use and which are what most investigators who

have published on the subject would consider the so-called gold standard, or whether bacterial vaginosis is confirmed by Gram stain, the bottom line is an alteration of the vaginal flora that is associated with an increased concentration of potentially pathogenic organisms. Patients with bacterial vaginosis are probably best identified clinically by means of composite clinical criteria, because this can be done in the office without having to wait to do the Gram stain, and many physicians may not do Gram stains in their offices. It seems that in looking at the correlations of Gram stain and composite clinical criteria with the diagnosis or microbiology of BV, it is probably best to use composite clinical criteria when making a diagnosis of bacterial vaginosis.

As far as whether abscess alone accounted for increases in the fever index and hospitalization, we still had an increase in the fever index as compared to people who were not infected, and we probably would not have had such a dramatic increase in hospitalization, but the people who were infected had an average stay of 8 days versus an average stay of 5 days for those who were not infected. There was a single readmission. Some of our previous work addresses the fact that unless patients are followed postoperatively after they have gone home from the hospital, all of the postoperative infectious complications may not be noted. We did not see any further problems except in one patient and that patient was included in the statistics. There were no acute infections or pyosalpinx or problems that we thought would predispose to infection or postoperative infection at the time of the original surgery.

It is interesting that a preparation other than povidone-iodine was mentioned for consideration. Indeed, Hibiclens or similar preparations may actually be better than povidone-iodine for sterilizing the vagina. Studies done on vaginal preparations have noted that there is an immediate decrease in the overall concentrations of bacteria, but by the time 30 minutes has elapsed concentrations have pretty much returned to normal. In an operation lasting a little more than 2 hours, it has not been unreasonable to assume that the flora is thriving almost as well as it was before the vaginal preparation was done.

Regarding Dr. Benrubi's statement about the Gram stain not correlating with clinical findings, I think it depends on what your gold standard is. We are actually in the midst of another study on bacterial vaginosis in which we are looking at Gram stains. The Gram stain can be a nice quality-control measure where if others are making the diagnosis of bacterial vaginosis and there is a so-called expert in this field, he or she can review the Gram stain to make sure that bacterial vaginosis is indeed the diagnosis.

Gardnerella vaginalis and *Mobiluncus* may well play a role in the pathogenesis of infection, and frankly any organism in the vagina, if present in high enough numbers and in a pure culture, can be a pathogen. We did not use perioperative antibiotic prophylaxis because we wanted a very clean study. For this reason we did not use vaginal hysterectomies, because we thought it was important that these patients not be given prophylactic antibiotics.

Cases with ruptured membranes that "reseal"

John W. C. Johnson, MD, Robert S. Egerman, MD, and Jacquelyn Moorhead, MStat
Gainesville, Florida

Among patients with a diagnosis of preterm prepartal rupture of the membranes, an occasional case ceases to leak amniotic fluid before the onset of labor. The purpose of this case-control study was to determine the characteristics and obstetric outcomes of this unique group of patients. This diagnosis was made in 24 such patients who gave birth in 1984 and 1985 at Shands Hospital. Compared with matched control subjects who continued to leak fluid, there were no significant differences in maternal race, age, marital status, socioeconomic status, smoking status, or past obstetric performance. Amniotic fluid volumes, as assessed by ultrasound studies, were less in the group that failed to "reseal." The "reseal" group had longer durations of pregnancy, larger babies, longer maternal hospitalization, less neonatal hospitalization, and less perinatal mortality and morbidity. The occurrence of "resealing" appears to bode well for the mother and infant. Such cases should be sought aggressively but managed conservatively. (AM J OBSTET GYNECOL 1990;163:1024-32.)

Key words: Ruptured membranes that "reseal," cessation of leakage of amniotic fluid, chorioamnion injury and repair

Preterm prepartal rupture of the membranes continues to be an obstetric enigma in terms of cause and management. This is a frequent problem that complicates 8% to 25% of all pregnancies.[1] Yet there are still major disagreements as to when intervention for delivery should occur and whether antibiotics, steroids, or tocolytic agents should be used.[1-3]

There is one outcome that occurs occasionally, which could have important implications in management. That is preterm prepartal rupture of the membranes with subsequent cessation of leakage of fluid and continuation of the pregnancy. We designate such patients as having had rupture of the membranes that "reseal," although other mechanisms could account for the discontinuation of vaginal amniotic fluid loss and remain to be evaluated. To our knowledge, the characteristics and prognosis of cases that "reseal" have not been described in detail. Information concerning these patients could prove useful in selecting the best management for preterm prepartal rupture of the membranes and might provide insight into the cause. The purpose of this study was to determine in our patient population the frequency of such cases, their epidemiologic features, their obstetric characteristics (including amniotic fluid volumes as assessed by ultrasonographic studies), and their clinical course.

Material and methods

This case-control study was performed in patients giving birth at Shands Hospital during the years 1984 and 1985. There were 24 study cases with a diagnosis of preterm prepartal rupture of the membranes that subsequently "resealed" with continuation of the pregnancy (study group). Twenty-four women who had preterm prepartal rupture of the membranes but did not "reseal" (control group) were matched to the study group with regard to gestational age at the time of rupture and approximate calendar month of rupture. Data were abstracted from the medical records and included: (1) demographic factors, vital statistics, and socioeconomic indicators; (2) details of past obstetric performance; and (3) characteristics and outcomes of the current pregnancy. All 24 of the study cases and the 24 control cases were singleton pregnancies. Therefore data concerning multiple gestations were excluded from these analyses.

The duration of pregnancy was assigned on the basis of the best estimate derived from menstrual data, early maternal physical examination, early ultrasonographic findings, and the infant's physical and neurologic development. The diagnosis of preterm prepartal rupture of the membranes was based on the history of sudden onset and continued vaginal leakage of fluid, which was confirmed by examination and positive ferning or alkaline testing with Nitrazine paper.[3] Patients with a diagnosis of prepartal rupture of the membranes were routinely hospitalized. In these patients the diagnosis of "resealing" was determined by daily inquiry of cessation of vaginal loss of fluid and by findings on speculum examination of absence of leakage and negative ferning or Nitrazine testing. Patients

with a diagnosis of "resealed" were discharged to outpatient care.

Ultrasonographic studies were performed routinely on most patients with suspected preterm prepartal rupture of the membranes at the time of admission with an ADR model 4000 scanner (Advanced Technology Laboratories, Inc., Bothell, Wash.) that used standard 3.5 or 5 MHz linear transducers. Amniotic fluid volumes were quantitated according to a previously described method.[4] An obvious but slight decrease was designated as "one arrow down." If there was fluid behind the fetal back, but the largest vertical pocket measured 3 to 5 cm, the interpretation was a moderate decrease in amniotic fluid volume, designated as "two arrows down." If there was no fluid behind the fetal back and the largest vertical pocket measured only 1 to 3 cm, the interpretation was a marked decrease, designated as "three arrows down." The most severe decrease in amniotic fluid (oligohydramnios) was diagnosed if there was no fluid behind the fetal back and the largest vertical pocket was less than 1 cm in depth. This was designated as "four arrows down."

Cervical or vaginal cultures for gonorrhea and group B streptococci were obtained on admission. In the event that either culture proved positive, appropriate antibiotic therapy was instituted. Otherwise, and in the absence of choreoamnionitis, antibiotics were not administered. As a general routine during 1984 and 1985, patients with preterm prepartal rupture of the membranes were not treated with tocolytic agents or steroids.

Group comparisons were made with regard to maternal age, past obstetric peformance, race, level of maternal education, marital status, and history of substance abuse. Comparisons were also made between the two groups with regard to: (1) admission characteristics including maternal habitus expressed as weight-to-height ratio, hematocrit, white blood cell count, and ultrasound estimates of amniotic fluid volumes and (2) outcome variables including length of gestation at delivery, fetal birth weight, fetal sex, Apgar scores, perinatal outcome including mortality and neonatal morbidity, and duration of maternal and neonatal hospital stays.

All statistical analyses were carried out by means of the Statistical Analysis Systems,[5] a computer software system for data analysis. For the continuous variables of interest a t test was performed to detect significant differences between the case and control group means. For nominal variables a χ^2 test was performed to test the independence of the outcome variable ("reseal") with the variables of interest. The Wilcoxon rank-sum test was performed for the ordinal response variables. Kendall's tau b test was used for significant linear associations. Since several tests were performed and the sample size was small, the Bonferroni inequality method was used to compute the appropriate level of significance ($p = 0.002$).[6]

Table I. Gestational age at onset of rupture

Gestational age at membrane rupture (wk)	*Preterm prepartal rupture of membrane, 1984-1985*		*p Value*
	"Reseal" (n = 24)	*Other (n = 184)*	
<28	5 (21%)	29 (16%)	0.7
≥28-32	6 (25%)	55 (30%)	0.7
≥32-<36	13 (54%)	100 (54%)	0.99

Results

During the years 1984 and 1985, a total of 24 cases of preterm prepartal rupture of the membranes that "resealed" were identified. This represents 0.4% of all 5937 deliveries, 2.8% of all 843 patients with prepartal rupture of the membranes, and 11% of all 208 patients with preterm prepartal rupture of the membranes.

Among the patients who "resealed," the distribution of gestational age on admission was essentially the same as that observed in all patients in 1984 and 1985 with a diagnosis of preterm prepartal rupture of the membranes that did not "reseal," (Table I). Since the 24 control patients were matched against the 24 "reseal" patients for gestational age at the time of membrane rupture, their gestational ages were identical.

All 48 patients in this pilot project had a history of recent onset of vaginal leakage of clear fluid. All "reseal" patients had either a positive fern test or a positive Nitrazine test. Both tests were performed in 22 of these study patients and both were positive in 17. Patients in the control group tended to initially have greater fluid volume losses by history and 22 had either a positive Nitrazine or a positive fern test result. Both tests were performed in 13 control patients and both were positive in 12. The diagnosis of cessation of amniotic fluid leakage was based on the patient's history and a repeat vaginal examination. No leakage was evident on inspection and all had either a negative fern or a negative Nitrazine test result. Fern tests were performed in 23 of these patients and all results were negative. Nitrazine tests were performed in 12 patients and results indicated acidity in 10. Among these patients the interval between rupture and "reseal" averaged 7.5 days with a range of 2 to 19 days.

Demographic characteristics (maternal age, race, and marital status), socioeconomic factors (level of education), and frequency of substance abuse (tobacco, alcohol, drugs) are presented in Table II for the study and control groups. No statistically significant differences were found between the two groups. However,

≥ 3 Aborted (<20 wk)	0.0 (n = 24)	8.3 (n = 24)	0.05
Height (in) (mean ± SD)	63.7 ± 2.86 (n = 24)	62.5 ± 3.92 (n = 23)	0.23
Weight (lb) (mean ± SD)	144.6 ± 25.47 (n = 24)	150.1 ± 30.78 (n = 20)	0.51
Weight (lb)/height (in) (mean ± SD)	2.27 ± 0.39 (n = 24)	2.42 ± 0.53 (n = 20)	0.29
White blood cell count (No./mm³) (×10³) (mean ± SD)	9.0 ± 2.25 (n = 20)	11.2 ± 3.56 (n = 22)	0.02
Hematocrit (%) (mean ± SD)	32.9 ± 3.53 (n = 22)	34.4 ± 4.16 (n = 24)	0.19

it is important to note that the groups were small and may not have been equivalent.

Table III shows the comparisons of prior obstetric outcomes, as well as the following admission characteristics at the time of initial diagnosis of preterm prepartal rupture: maternal habitus (expressed as weight-to-height ratio), white blood cell count, and hematocrit. Among the control group, 8.3% had a history of three or more previous miscarriages, which was more frequent than the 0% incidence of the study group. The mean white blood cell count on admission tended to be higher for the control group than the "reseal" group. Neither of these trends was statistically significant at a p value of 0.002.

Amniotic fluid volume estimates were performed on admission for all of the patients who "resealed" and 13 of the patients who did not "reseal." The percentages of patients with each of the various quantifications are shown in Fig. 1. Severe reductions in amniotic fluid volumes (↓ ↓ ↓ ↓) were more common in the assessed control patients than in the study patients (69% compared to 4%; $p < 0.0004$). Within the group that "resealed," no significant correlations were found between amniotic fluid volume estimates and (1) the interval from premature rupture of membranes until delivery ($r = 0.29$; $p = 0.15$), (2) birth weight ($r = 0.31$; $p = 0.15$), or (3) gestational age at delivery ($r = 0.26$; $p = 0.22$).

Among the group that "resealed," three were found to have positive vaginal cultures for group B streptococci and all were treated with ampicillin. None of the study patients received tocolytic agents. Among the control population tested, there were no positive cultures for group B streptococci or gonorrhea at the time of admission. Two of the control patients received intravenous β-sympathomimetics. One received intravenous terbutaline to no avail. A second received intravenous ritodrine during transfer, but this was discontinued on arrival at Shands Hospital.

Table IV lists the outcomes in both groups for mean length of gestation at delivery, birth weight, 1-minute and 5-minute Apgar scores, neonatal mortality and morbidity (expressed as frequency of respiratory distress and hyperbilirubinemia), duration of neonatal hospitalization, and duration of maternal hospitalization. The mean length of gestation at delivery in the "reseal" group was significantly longer than that in the control group (Table IV and Fig. 2). Five inductions were performed in the study group. Three were for preeclampsia, one was for a postterm pregnancy, and the fifth was for spontaneous rupture of the membranes at term with prolonged latency. There were five cesarean sections (21%). Two were performed because of arrested active phase of labor, two for fetal distress, and one because of breech presentation. There were no inductions performed in the control group, although four cesarean sections (17%) were performed. The indications were fetal distress (two patients) and breech presentation (two patients).

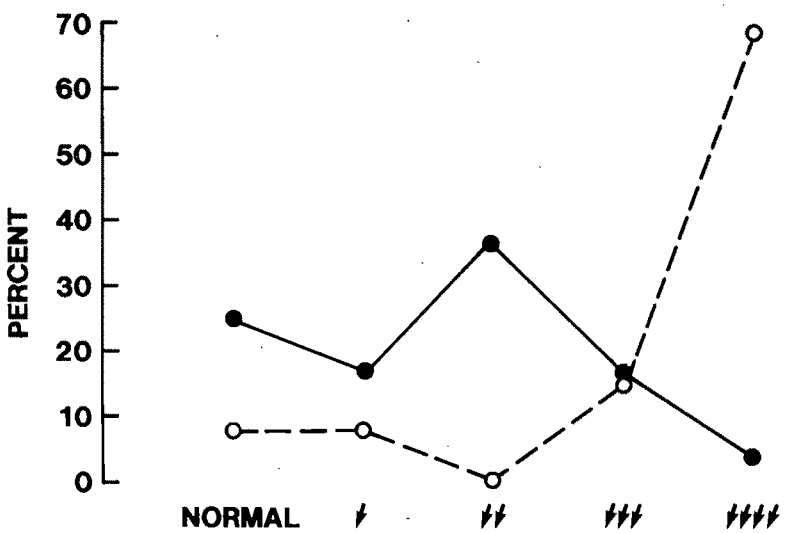

Fig. 1. Graph showing amniotic fluid volume estimates by percentage distributions in "reseal" group *(closed circles)* and control group *(open circles). One arrow down,* Slight decrease; *two arrows down,* moderate decrease; *three arrows down,* marked decrease; *four arrows down,* severe decrease (see text for ultrasonographic method for quantifying fluid volumes). Control group had significantly higher proportion of patients with severely decreased amniotic fluid volumes than "reseal" group ($p < 0.0004$).

Table IV. Obstetric outcome

Variable	*Group*		*p Value*
	"Reseal"	*No "reseal"*	
Gestational age at premature rupture of membranes (wk) (mean ± SD)	29.9 ± 5.3 (n = 24)	29.9 ± 4.9 (n = 24)	
Gestational age at delivery (wk) (mean ± SD)	38.3 ± 2.7 (n = 24)	30.5 ± 4.8 (n = 24)	0.0001
Birth weight (gm) (mean ± SD)	2977 ± 789 (n = 24)	1682 ± 703 (n = 24)	0.0001
1 min APGAR score (mean ± SD)	7.8 ± 1.8 (n = 24)	5.9 ± 3.1 (n = 24)	0.01
5 min APGAR score (mean ± SD)	8.5 ± 1.5 (n = 24)	6.9 ± 3.0 (n = 24)	0.02
Neonatal hospital stay (days) (mean ± SE)	3.3 ± 0.7 (n = 24)	16.4 ± 3.4 (n = 23)	0.01
Respiratory distress (No.)	3 (12.5%)	11 (45.8%)	0.01
Hyperbilirubinemia (No.)	4 (16.7%)	14 (58.3%)	0.003
Fetal neonatal death (No.)	0 (0.0%)	4 (16.7%)	0.11
Maternal hospital stay (days)	10.5 (n = 24)	4.1 (n = 24)	0.025

The distribution of gestational ages at the time of delivery are listed in Table V for both groups. Thirty percent of the "reseal" patients gave birth prematurely (<37 weeks), whereas 100% of the control patients gave birth prematurely ($\chi^2 = 13.6$ with Yate's correction; $p < 0.001$). The mean birth weight of the "reseal" group was significantly greater than that of the control group (Table IV and Fig. 3). Among the "reseal" patients, three infants had body weights below the tenth percentile corrected for gestational age and three infants had birth weights above the ninetieth percentile corrected for gestational age, probably reflecting a normal distribution for these near-term deliveries. All of the infants in the control group had birth weights appropriate for gestational age.

The study group had no perinatal deaths, whereas the control group had four perinatal deaths (perinatal mortality rate = 167/1000) (Table IV). But the difference in absolute numbers of perinatal deaths was not statistically significant ($\chi^2 = 2.8$, Yates' correction; $p < 0.2$). The trend to lower mean Apgar scores at 1 minute and 5 minutes in the neonates in the control group may be attributed to the higher frequency of prematurity. Unfortunately umbilical blood acid-base studies

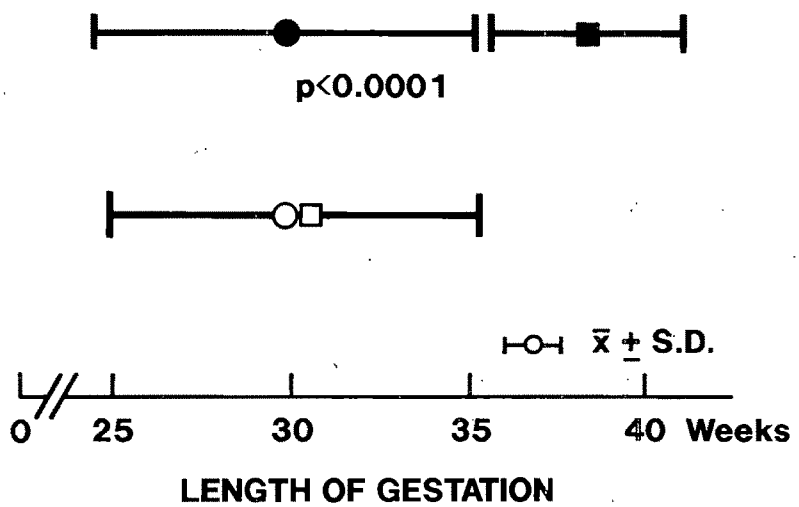

Fig. 2. Graph showing mean (±SD) lengths of gestation at rupture of membranes *(circles)* and at time of delivery *(squares)*. *Solid symbols* represent "reseal" patients; *open symbols* represent control patients. Difference between gestational ages of two groups at delivery was significant ($p < 0.0001$).

Table V. Gestational ages at delivery

Gestational age (wk)	*Preterm prepartal rupture of membranes, 1984-1985*				*p Value*
	"Reseal" (n = 24)		*Control (n = 24)*		
	No.	*%*	*No.*	*%*	
<28	0	0	5	21	0
≥28-<32	1	4	6	24	0.1
≥32-<36	2	8	13	54	0.01
≥36	21	88	0	0	0.001

were not done in sufficient numbers to permit comparisons.

Fifty-eight percent of the infants in the study group were male, as were 54% of the infants in the control group. Neonatal respiratory distress and hyperbilirubinemia tended to occur more often in the control group (Table IV). These and other prematurity problems could account for the trend to longer neonatal hospitalization in the control population (Table IV and Fig. 4). The total duration of hospitalization for the mothers in the study group averaged 10.5 days per patient (range of 3 to 51 days) and tended to be longer than that for the mothers in the control group, which averaged 4.1 days per patient (range of 1 to 9 days) ($p = 0.025$). Two mothers in the control group who gave birth vaginally had a diagnosis of postpartum endometritis and both responded to antibiotic therapy. Within the "reseal" group, four mothers had postpartum endometritis (two vaginal deliveries and two cesarean sections) that responded to antibiotics satisfactorily.

One control patient gave birth with a 20% abruptio placentae at 32 weeks' gestation (after a latent period of 2 days). Another had postpartum hemorrhage severe enough to require blood transfusion. Aside from the duration of maternal hospitalization, maternal morbidity was not thought to be clinically different between the two populations.

Comment

To our knowledge "resealing" in the case of spontaneous rupture of the membranes has not been previously reported in detail. In the 1% to 2% of genetic amniocenteses that may be complicated by vaginal leakage of amniotic fluid, subsequent cessation of leakage and successful completion of the pregnancy has been reported.[7, 8] Gold et al.[9] reported their experience in which six of seven patients (86%) with fluid leakage after second-trimester amniocentesis subsequently ceased leaking and gave birth at term uneventfully. They cited an abstract from the University of Utah Medical Center in which 18 of 22 patients (86%) with amniotic fluid leakage after second-trimester amniocentesis subsequently had "normal outcomes" (Baty B, Weinblatt B. Amniotic fluid leak after second trimester amniocentesis. Proceedings of the NSCG Educational Conference, New Orleans, La., 1988). Yet such outcomes are not commonly acknowledged to occur in the case of spontaneous rupture of the membranes. This raises the question of whether the present large series of cases may represent overdiagnoses.

Garite[10] has stated that history alone gives a correct diagnosis of prepartal rupture of the membranes in 90% of patients. The remaining 10% could have urinary incontinence or vaginitis. It seems unlikely that in

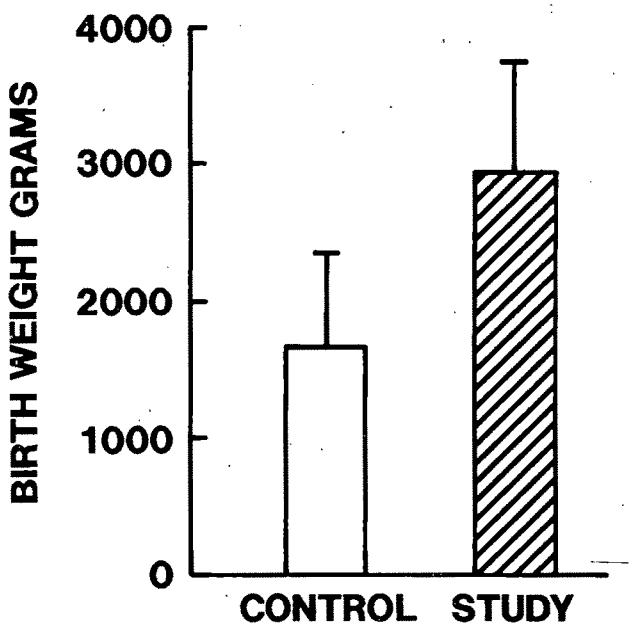

Fig. 3. Mean (±SD) birth weight of "reseal" patients *(cross-hatched column)* was significantly higher than that of control patients *(open column)* ($p < 0.0001$).

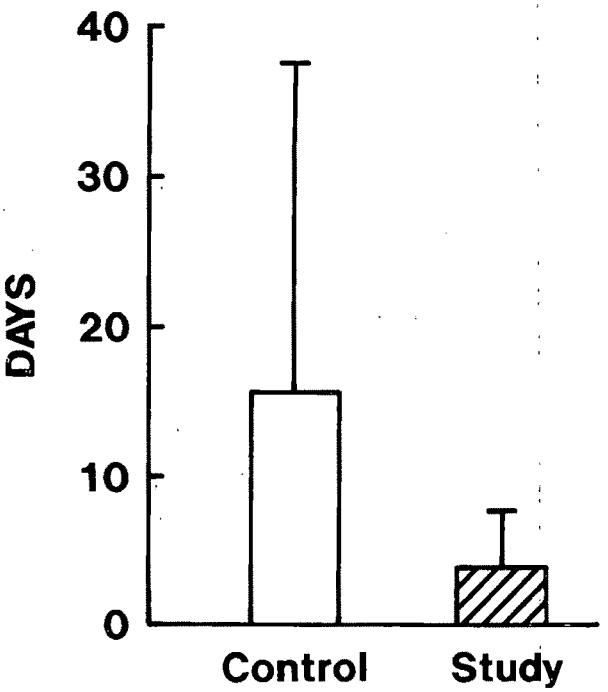

Fig. 4. Mean (±SD) duration of neonatal hospitalization was less in "resealed" group *(cross-hatched column)* than in control group *(open column)*.

the present series patients would initially have either urinary incontinence or vaginitis of sudden onset, would have positive fern or Nitrazine tests, and would then subsequently cease "leaking" without specific treatment. Also the gestational age distribution at diagnosis of rupture for the "reseal" group was very similar to that observed for the total 1984 and 1985 Shands' population that did not "reseal" (Table I). In addition, the demographic and admission features of the "reseal" group appeared to be very similar to those of the matched control population (Tables II and III).

The normal amniotic fluid volumes reported in 25% of our study group do not preclude the diagnosis of spontaneous prepartal rupture of the membranes, since our own experience (Fig. 1) and that of others[11] indicate that spontaneous prepartal rupture of the membranes may be present with normal fluid volumes as assessed by ultrasonographic examination. The 58% frequency of moderate-to-severe decreases in amniotic fluid volumes, (↓ ↓, ↓ ↓ ↓, and ↓ ↓ ↓ ↓) noted on ultrasound in the study group was significantly higher ($\chi^2 = 93$; $p = 0.0001$) than the 5.6% observed in a Shands Hospital population without ruptured membranes.[4] These findings argue against overdiagnosis and support our assertion that these 24 study patients had ruptured membranes. It is possible that the 11% frequency of "resealing" noted in this report is unique to this patient population, but Amon et al.[12] recently reported that the "leaking stopped" in 12% to 13% of their patients with preterm prepartal rupture of the membranes. Additional populations should be studied to establish the frequency of this event.

The outcome data indicate that "resealing" is a desired event. Certainly the results in the neonates were improved. The 12.5% frequencies of fetal growth retardation and macrosomia in the "reseal" group are not much different from the tenth percentile distribution expected in the normal population. Still these frequencies tend to be greater than those observed in the control group. Further studies might establish whether these differences are clinically significant. Commonly feared complications of spontaneous rupture of the membranes, such as chorioamnionitis, abruptio placentae, and septic shock, did not appear to occur with increased frequency in the "reseal" group. Furthermore, the net cost of care would seem to be less in the patients who "resealed." Assuming $1000 per day for neonatal intensive care and $500 per day for maternal care, the net costs for a "reseal" patient would average about $10,300 less per mother and neonate.

Since the rupture-to-reseal interval averaged 7.5 days, it is possible that a more appropriate control group would be one that did not labor for at least 1 week after rupture. Were it possible to adjust for this variable, the magnitude of outcome differences might have been reduced. However, we suspect the "reseal" neonates would still have better outcomes, since the "reseal-to-delivery" interval averaged 7 weeks.

We looked carefully for clinical factors that might influence the advent of "resealing." Of the many epidemiologic and obstetric factors we examined, only amniotic fluid volumes after rupture seemed to be different. We were unable to detect any evidence that infection might prevent "resealing," but we may not have tested for the appropriate indicators.

It seems likely that the smaller the membrane defect resulting in leakage of fluid, the greater the chance of "resealing." The high frequency of "resealing" in genetic amniocentesis favors this hypothesis.[7-9] Even the frequency of overt leakage reported in genetic amniocentesis seems to vary directly with the size of the needle used.[7, 8] In the current study group, the higher prevalence of normal or slightly reduced amniotic fluid volumes suggests that a small aperture promotes "resealing." However, we were unable to demonstrate significant correlations between estimated fluid volumes on admission and the interval until delivery or the gestational age at delivery, in the "reseal" group.

Whether there are therapeutic measures that would enhance or deter the probability of "resealing" remains to be determined. Limited activity and bed rest may favor the reparative process, but to our knowledge no studies have addressed this issue. Also the effect that steroid therapy given to accelerate fetal lung maturity might have on the membrane "resealing" process is unknown.

In summary, a series of patients with the diagnosis of preterm prepartal rupture of the membranes subsequently ceased to leak fluid, continued to carry their pregnancies, and had improved obstetric and neonatal outcomes. In this case-control study we found no clinical factors associated with "reseal" except larger post-rupture amniotic fluid volumes. The frequency of "resealing" must vary among obstetric populations. However, it would appear to be important to search diligently for such cases, since expectant therapy yields excellent results.

Discussion

DR. JAMES F. CARTER, Georgetown, South Carolina (Official Guest). Preterm prepartal rupture of the membranes continues to provoke great controversy in obstetrics and gynecology, perhaps because of our inability to both satisfactorily predict and to unfortunately successfully treat this obstetric nightmare in many instances. There are few diagnoses in obstetrics that elicit more concern and anxiety in the clinician.

We have all experienced the anecdotal events of our patients' membranes appearing to reseal. I am not aware of any report that has previously tried to quantitate these events with subsequent prognosis and identification of risk factors.

Dr. Johnson's methodology to match 24 women who had preterm prepartal rupture of the membranes that subsequently resealed (study group) with 24 women with preterm prepartal rupture of the membranes (control group) that did not reseal to the gestational age at the time of rupture and the approximate date of delivery was certainly well thought out. Data abstracted from the records, including demographic factors, vital statistics, socioeconomic indicators, and details of past obstetric performance, gave valuable information in comparison. To simplify the comparison, all pregnancies were singleton.

One of the keys to the study would of course be the accurate diagnosis of rupture of the membranes, and this diagnosis was made quite thoroughly by the means noted, including examination and positive fern-ing and/or results of Nitrazine testing. Because of Dr. Johnson's reference, I assumed that the examination of course would be by sterile speculum. This technique of course is paramount to the examination at the time. The combination of this thorough examination would

be paramount to refuting any skeptic that the rupture of the membranes was the result of vaginitis, urinary incontinence, or both, as Dr. Johnson's study pointed out. I believe this was addressed clearly and concisely.

In an effort to rule out infections as a possible cause and to treat only if positive, cultures were obtained for gonorrhea and group B streptococci, and antibiotic therapy was begun only if positive. It would have been interesting to combine this fact with additional information on the outcome of treatment with tocolytic agents or steroids. What comes to mind would be whether steroids in fact prevented or delayed or decreased the actual percentage of the resealing. It would be interesting to see if the steroids actually decreased the percentage of resealing in patients receiving them. This issue, as pointed out by Dr. Johnson, was not addressed and was not the subject of this article.

Further comparisons were made in regard to maternal age, past obstetric performance, race, level of education, marital status, and substance abuse history. This information was quite thorough. In addition, information that is oftentimes anecdotally reflected on but never, to my knowledge, quite quantitated includes data such as the height versus weight ratio. Hematocrit, white blood cell count, ultrasonographic estimates of amniotic fluid, gestational age at delivery, fetal birth weight and sex, and Apgar scores in perinatal outcome including the mortality and neonatal morbidity were also included. It would have also been interesting to compare the caloric intake of these two groups, which may parallel a positive or negative nitrogen balance. Although this information would be difficult to quantitate objectively, determination of albumin and total protein levels on a multiple serum analysis may be helpful and would certainly be interesting. In general, Dr. Johnson's method was well thought through and gave a valuable objective comparison and may have confirmed or rejected many of our preconceived ideas about the demographics of these two groups.

More and more clinicians are becoming increasingly aware of the importance of amniotic fluid volumes, both in the diagnosis of preterm prepartal rupture of the membranes and in the prognosis. This aspect has recently been discussed in the literature to various degrees of specificity. In this report the numbers have been quantitated, which should help keep this potential resealing event, although the incidence is low, in the forefront of every clinician's mind. Dr. Johnson's group has also made the point that although conservative management may in fact prolong the maternal hospital stay, the decrease in the neonatal hospital stay more than makes up for this conservative approach.

The conservative management is sound obstetric practice, and from a cost-benefit standpoint this report gives the clinician further clout in the ongoing battle with third-party payers who constantly pressure physicians to discharge these patients.

Dr. Johnson's study looked at many risk factors in an effort to identify any fact that may help locate any of these patients that may have a tendency to reseal and therefore improve the neonatal outcome. Many obstetricians are reluctant to engage in conservative management, perhaps partly because they are near level III centers or perhaps because of their fear of increasing maternal morbidity or mortality. Dr. Johnson's article was reassuring in that there was not thought to be any clinically significant difference in mortality and morbidity between the two groups.

One would assume that resealing is a desired event. Dr. Johnson's study would appear to support this assumption; clearly the data show that the larger the amniotic fluid volume, the greater the chance for resealing to occur. Other epidemiologic data did not appear to offer any other suggestions for predicting the resealing, which although somewhat discouraging should not prevent us from continuing to seek out other possible causes as predictors of resealing of the membranes, because it does have such excellent neonatal outcomes in comparison to the patients who fail to reseal.

Continuing this search may enable us to identify therapeutic measures that may be helpful in achieving a better outcome that this study was not able to identify.

One would hope that Dr. Johnson's paper would encourage all of us to seriously consider conservative management of preterm prepartal rupture of membranes, especially in those patients with larger volumes of amniotic fluid. It may also encourage obstetricians who are not ultrasonographers to involve our radiologist colleagues early in the clinical course to help them with any clinical decisions regarding the volume of amniotic fluid. This early and aggressive approach to the evaluation of these patients with ruptured membranes would only help to identify these same patients and help to aggressively seek out this patient population, which although small, has such an excellent perinatal outcome. I think that greater awareness of the options offered by these types of approaches to patient management may be a significant addition to our practice.

DR. FRANK GREISS, Mooresville, North Carolina. When did you do the analysis of the amniotic fluid volume? Did you do it immediately or later?

DR. JOHNSON (Closing). I agree with Dr. Carter that it would be interesting to have a better idea about the nutritional status of these patients, since that characteristic could have some bearing on the tendency to reseal. About the only way to achieve this is to look at body habitus and the weight distribution to the height of the patient, although that is certainly a very inaccurate measure of nutritional status. The fact that anemia did not seem to be more common in either population seems also a crude indication that their nutritional status was comparable. In answer to Dr. Greiss' question, in general the amniotic fluid volume estimates were done shortly after the diagnosis of rupture of the membranes and certainly within 1 to 2 days after admission.

The use of serial CA 125 concentrations to monitor endometriosis in infertile women

Donald E. Pittaway, MD, PhD
Winston-Salem, North Carolina

To evaluate the potential use of CA 125 concentrations in monitoring women with endometriosis, serial determinations were correlated with the clinical course of the disease and pregnancy rates. Preoperative CA 125 concentrations were obtained in 134 consecutive infertile women with endometriosis. Seventy-six (57%) women had values ≥16 U/ml and were followed up for 18 months. At the 6-, 12-, and 18-month intervals, pregnancies occurred in 18 of 45 (30%), 14 of 24 (58%), and 5 of 12 (42%) women in the good prognosis group, respectively; pregnancy rates in the poor prognosis group were 1 of 31 (3%), 2 of 33 (6%), and 0 of 26 (0%) women ($p < 0.001$). Changes in the CA 125 values correlated with the surgical findings in 24 of the 26 women (92%) who had a second-look operative procedure. The study supports the use of serial CA 125 concentrations to assist in the management of women with endometriosis. (AM J OBSTET GYNECOL 1990;163:1032-7.)

Key words: CA 125, endometriosis, infertility

Endometriosis frequently persists or recurs after treatment,[1-3] and often cannot be detected or differentiated by pelvic examination from postsurgical changes. Also, occult foci may be missed even at laparoscopy or laparotomy and result in incomplete surgical removal or destruction of the endometriosis.[4] Consequently, endometriosis often presents a difficult diagnostic and therapeutic challenge to the clinician.

Recently, elevations of CA 125, a serum marker for human epithelial ovarian cancer, have been observed in women with endometriosis.[5-7] In addition, the serum concentrations of CA 125 have been observed to correlate with the clinical stage and the clinical course of the disease,[7, 8] and an earlier study has suggested that the changes of CA 125 may have predictive value for pregnancy.[9] Consequently, this prospective study was undertaken to evaluate further the usefulness of serial determinations in monitoring infertile women after the diagnosis and surgical treatment of endometriosis.

Material and methods

Preoperative CA 125 concentrations were obtained in 134 consecutive infertile women with endometriosis from whom informed consent had been obtained. Seventy-six (57%) women had values ≥16 U/ml (which is considered elevated in our laboratory), and were followed up for 18 months. Twenty-six of 41 women who

had not conceived underwent a second operative procedure between 12 to 18 months (19 conservative and seven hysterectomy). The characteristics of the initial study population and the subgroup with elevated CA 125 concentrations are listed in Table I. Preoperative evaluation of the couples included semen analysis, postcoital testing, hysterosalpingography, and endometrial biopsy specimen. The surgical treatment of endometriosis was performed by the author and individualized to either operative laparoscopy with electrocoagulation and/or carbon dioxide laser, or conservative laparotomy. The severity of the endometriosis was staged according to the revised American Fertility Society classification.[10] In women with endometriomata, danazol (800 mg/day) was administered for 3 months after surgery. Two patients required donor insemination for a significant male factor, and eight received clomiphene citrate to correct either oligoovulation (five women) or luteal inadequacy (three women).

CA 125 was measured in duplicate with an immunoradiometric assay (Centocor, Malvern, Pa.), which has been modified for use in women with endometriosis, and previously described in detail.[11] The CA 125 levels were not used to influence management decisions, and were evaluated at the completion of the study. The women were considered as having a good prognosis if the postoperative CA 125 concentrations decreased by at least 40% to levels <16 U/ml. Women whose CA 125 concentrations failed to meet these criteria initially or whose levels later increased to ≥16 U/ml, suggesting recurrence, were placed in a poor prognostic group. The data were evaluated with a χ^2 analysis with Yates' correction, and Fisher's exact test. Correlation of the changes in CA 125 values with the clinical course were analyzed with the use of the κ test.[12] A p value < 0.05 was considered statistically significant.

Results

In Figs. 1 and 2 are shown the flow charts for the 45 women in the intial good prognostic group and the 31 women in the initial poor prognostic group, respectively. The number of women in each prognostic group and the number of women who achieved pregnancy are indicated at 6-month intervals. The combined pregnancy rates at the 6-, 12-, and 18-month intervals were 19 of 76 (25%), 16 of 57 (28%), and 5 of 38 (13%) women. During the same time intervals, pregnancies occurred in 18 of 45 (30%), 14 of 24 (58%), and 5 of 12 (42%) women in the good prognostic group, and in 1 of 31 (3%), 2 of 23 (6%), and 0 of 26 (0%) women in the poor prognostic group ($p < 0.001$).

The pregnancy rates at 12 months are listed in Table II, according to the stage of endometriosis at the initial procedure.

Overall, the pregnancy rates were significantly higher in the good prognostic group ($p < 0.001$), and this difference achieved statistical significance in both the moderate ($p < 0.001$) and severe ($p < 0.02$) stages of endometriosis.

*Revised American Fertility Society classification.[10]

The surgical findings in 24 of 26 women (92%) who had a second-look procedure correlated with the changes in the CA 125 values ($p < 0.001$). Endometriosis was found in 23 women, and the two women in whom the values did not correlate had mild disease that was not suggested by values of CA 125, which were <16 U/ml.

Comment

This study confirms and extends the observations in 100 infertile women with endometriosis who were followed up for 1 year.[9] In this earlier investigation, women with elevated preoperative CA 125 concentrations had significantly lower pregnancy rates (45%) than those of women with nonelevated levels (63%). The changes in CA 125 levels had no predictive value in women with nonelevated preoperative concentrations. However, the pregnancy rates were significantly lower in women with elevated preoperative levels whose CA 125 concentrations failed to decrease as compared with the pregnancy rates of women whose concentration decreased. For this reason, a group of women with elevated preoperative CA 125 levels were selected to be followed up until pregnancy occurred or up to 18 months after treatment. In this study, the predictive value of the changes in the pre- and postoperative CA 125 concentrations was again observed, but in addition,

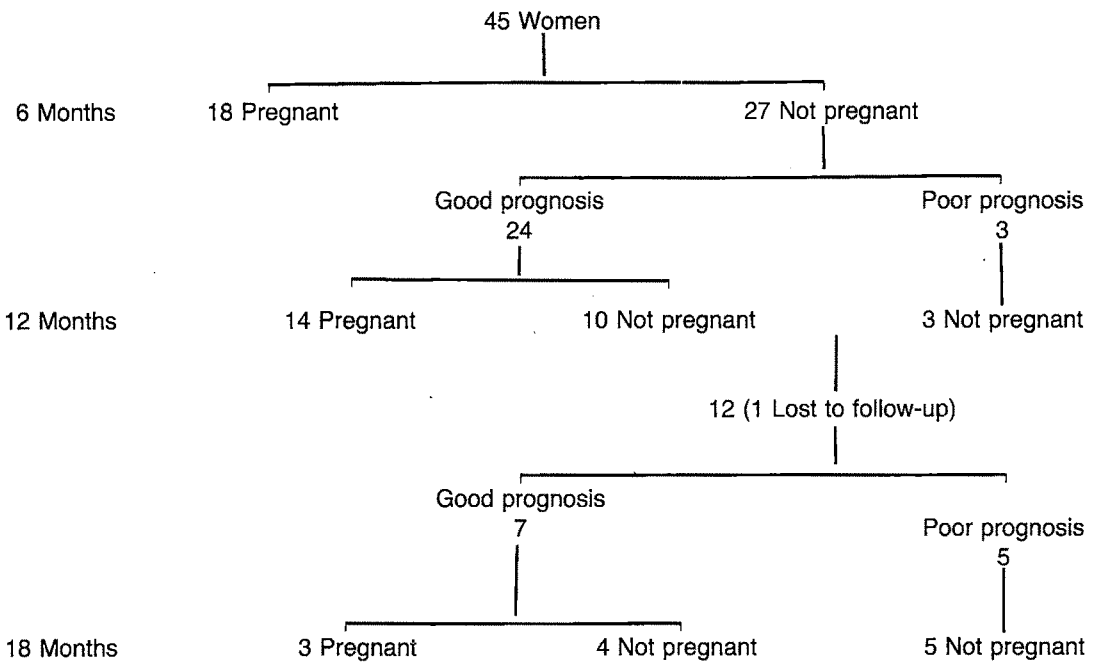

Fig. 1. Flow chart for the initial good prognostic group

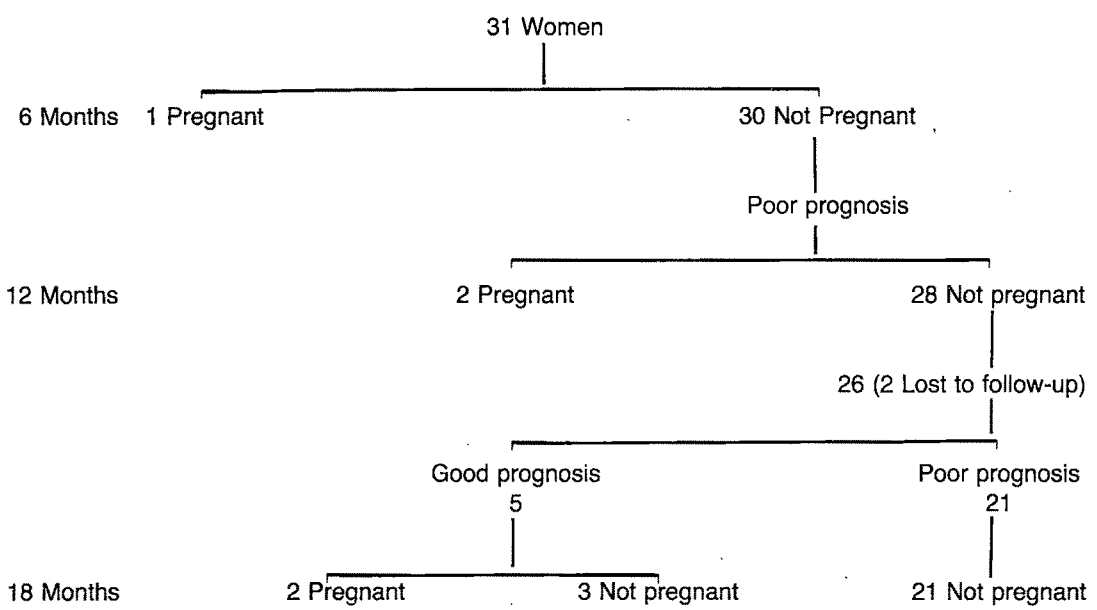

Fig. 2. Flow chart for initial poor prognostic group.

subsequent spontaneous changes such as an increase in levels or changes after retreatment with a reduction in levels also have predictive value for subsequent pregnancy rates.

A high degree of correlation between the surgical findings at a second-look procedure and the changes in CA 125 was found as was seen also in previous observations.[7, 8] However, the degree of correlation is probably inflated because of a number of methodologic biases in the present study. First, only women who had not conceived after 1 year were candidates for a second-look procedure, and second, not all these women were surgically evaluated. Third, women who had obvious recurrence by pelvic examination or symptoms consistent with recurrence would be more likely to undergo another surgical procedure, which is further supported by the high proportion of women who received hysterectomy in this group. Nonetheless, a significant

Table II. Pregnancy at 12 months according to stage of endometriosis

Stage	Good prognosis		Poor prognosis		Total		p Value
	No.	Pregnant (%)	No.	Pregnant (%)	No.	Pregnant (%)

TOTAL	45	32 (71)	31	3 (10)	76	35 (46)	<0.001

change in CA 125 concentrations as defined in this study correlated with the status of the endometriosis in most of the women.

Approximately 50% to 60% of women with endometriosis have CA 125 levels ≥16 U/ml in our experience as a surgically oriented university-based referral practice.[7-9] With modification of commercially available assays, serial CA 125 determinations in this group of women appear to offer useful information about the status of endometriosis and the likelihood of achieving a pregnancy after surgical treatment. The changes in CA 125 could be used together with clinical parameters to assist in deciding whether and when surgical or medical retreatment should be considered. Women with a persistently poor prognostic profile of CA 125 values could be counseled to encourage them to think about one of the new technologic approaches such as in vitro fertilization or to begin the adoption process. How much the use of serial CA 125 determinations will assist or improve the overall management of endometriosis will require the results of randomized, prospective studies.

Discussion

DR. JOHN A. BURIGO, West Palm Beach, Florida (Official Guest). Dr. Pittaway presented an excellent paper correlating the serum level of CA 125 with the likelihood of achieving pregnancy in patients treated for endometriosis. Most of us associate the clinical use of CA 125 with the diagnosis and management of patients with epithelial ovarian cancers. However, we know that elevations of serum CA 125 can also be associated with some normal physiologic conditions and disease states other than ovarian cancer. Elevations are associated with other malignancies including those of the endometrium, fallopian tube, breast, liver, lung, and pancreas, as well as with benign conditions including endometriosis, pelvic inflammatory disease, pleuritis, pericarditis, and pancreatitis. Elevations are also associated with nonpathologic conditions such as pregnancy and menstruation.

Dr. Pittaway's interest in the correlation between elevations in the serum level of CA 125 and conditions other than ovarian carcinoma precedes this study. In a previous paper he reported the correlation between elevated CA 125 and endometriosis.[1] In that study he reported that the degree of elevation of the antigen correlated significantly with the severity of disease and that changes in the clinical course of patients with endometriosis correlated with changes in the level of circulating antigen. In a more recent study he found that the level of serum CA 125 could be useful in distinguishing between patients with pelvic pain caused by endometriosis versus other causes of pelvic pain.[2] He reported that a CA 125 level ≥16 U/ml correlated with the presence of endometriosis in 80% of the patients and only 6% of patients with elevations had causes for

pelvic pain other than endometriosis. Thus he established a discriminatory value of CA 125 that would be predictive of the presence of endometriosis.

In the current study Dr. Pittaway studied a group of 134 infertile patients. From the initial group he segregated 76 patients who had an elevated level of CA 125, defined as 16 U/ml by his previous publication. His evaluation incuded either laparoscopy with electrocoagulation and/or laser or conservative laparotomy. After surgical evaluation and treatment, each patient had a repeat CA 125 evaluation, and were then classified into either a good or poor prognostic group on the basis of their level. It would be interesting to know how the decision was made regarding operative technique and whether there was a difference in the percentage of patients who converted from the poor to the good prognostic group related to the operative technique that was chosen.

Pregnancy rates were recorded at 6-month intervals for 18 months. The results indicate that the pregnancy rate was significantly higher in the good prognostic group. However, when analyzed by the stage of endometriosis the difference was significant only for those patients with moderate and severe disease. The absence of a significant difference in the patients with minimal and mild disease is disturbing because this group would comprise the majority of patients being seen by the average clinician. I wonder whether Dr. Pittaway would be willing to comment on why the pregnancy rate was not significantly different in lower stages.

He reported that there were 10 patients who received additional therapy for coexisting causes of infertility. He did not tell us whether these patients weighed more heavily on one prognostic group or the other, which could have affected the pregnancy rate within that group.

It would be interesting to know what percentage of the patients with endometriomata who were treated with a 3-month course of danocrine, converted from the poor prognostic group to the good prognostic group.

In his comment Dr. Pittaway suggested that patients with a persistently poor prognostic profile of CA 125 level could be encouraged to pursue adoption or alternative approaches such as in vitro fertilization. With regard to in vitro fertilization, I wonder whether he would be concerned that those patients with persistently elevated antigen are more likely to have residual endometriosis and that immunologic factors in the serum of these patients[3] might lessen the success rate of an in vitro procedure. Perhaps an alternative would be to take those patients who remain in the poor prognostic group after initial surgery and recommend either immediate reoperation for further debulking or medical therapy with gonadotropin-releasing hormone analog, danocrine, or tamoxifen citrate, hoping that they will then convert to the better prognostic group with its associated higher pregnancy rate.

I thank Dr. Pittaway for his excellent presentation and for his earlier work on this topic. The frustration and anxiety experienced by infertile couples increases with the passage of time during their evaluation and treatment. The information presented by Dr. Pittaway enables us to identify a population of patients after the surgical treatment of endometriosis who require additional action. It is hoped that future publications will identify a course of action that will enable us to help these patients to expeditiously achieve their goal.

DR. BARRY VERKAUF, Tampa, Florida. Dr. Pittaway, have you had the opportunity to follow up CA 125 levels in untreated patients with endometriosis over time and make observations on their stability?

DR. PITTAWAY (Closing). With regard to the surgical technique, this was a clinical study and techniques were really decided on the basis of individualizing with regard to the patient's disease. The majority of the patients underwent laparoscopic treatment. The only relationship to the outcome that was noted was that patients who required conservative laparotomy because of more significant disease were more likely to have persistent or recurrent disease. With regard to the nonstatistically significant difference in the minimal or mild disease, as I mentioned, I would attribute this to the small numbers, and I think if we had had larger numbers the trend that is noted may eventually change the statistical significance. With regard to the information that we provided in the poor prognostic group, I believe that their chances of conceiving over 6, 12, 18 months is very low, and alternatives should be discussed with this group of patients. This would include retreatment, in vitro fertilization, or consideration of adoption. With respect to in vitro fertilization, patients with minimal or mild disease do very well with in vitro fertilization protocols, and in fact are very good candidates with good prognoses. In patients with active disease, particulary with significant ovarian involvement, treatment of the endometriosis is probably worth considering, probably going ahead with in vitro fertilization. The most recent results that have just been published in *Fertility and Sterility* have indicated a delivered pregnancy rate of approximately 12%.[1]

Dr. Verkauf asked about CA 125 levels in patients with untreated endometriosis and patients without endometriosis at all. We have a small number of patients that we followed up over a number of years. In patients without endometriosis the level stays fairly stable. In other words, if the level is approximately 10 U/ml, it will stay approximately 10 U/ml. In patients with endometriosis, particularly those with minimal or mild

disease, we have not had to re-treat them. Again, the levels stay fairly stable unless there is recurrence or progression of disease. We have an ongoing study looking at a number of these patients in which we will correlate second-look data on a separate basis. This appears to show a very good correlation with a rising pattern with the presence or advancement of disease. With most patients who have mild disease we are not pushed to re-treat them as long as the level stays about the same; we continue to monitor them on the basis of clinical information and the CA 125 value.

Multiple endocrine adenomatosis type I in pregnancy

Alexander R. Smythe II, MD, Kay F. McFarland, MD, Mohammed Yousufuddin, MD, and William D. Meredith, MD

Columbia, South Carolina

A 26-year-old woman, gravida 1, para 0, having episodes of confusion, slurred speech, and blurred vision in pregnancy was documented to have severe hypoglycemia with elevated serum insulin and C-peptide levels. Emergency treatment for hypoglycemia was necessary several times during pregnancy. A healthy female infant was delivered after oxytocin induction of labor. Post partum the patient had numerous episodes of severe hypoglycemia in spite of constant intravenous glucose. Computerized tomographic scan of the pancreas failed to show a lesion, whereas pancreatic arteriography revealed a 2 cm mass in the tail of the pancreas. Partial pancreatectomy was performed 6 days after delivery. Microscopic examination of the tissue confirmed the presence of an insulinoma. Hypercalcemia developed together with elevated parathyroid hormone levels. The presence of an insulinoma, hypercalcemia, and a history of hyperparathyroidism in two relatives indicates that this is a case of multiple endocrine adenomatosis type I first diagnosed during pregnancy. (Am J Obstet Gynecol 1990;163:1037-9.)

Key words: Insulinoma, endocrine adenomatosis

We describe a case of multiple endocrine adenomatosis type I that was first diagnosed during pregnancy.

Case presentation

A 26-year-old, white woman, gravida 1, para 0, was admitted to the hospital at 16 weeks of gestation with symptoms of confusion, slurred speech, and blurred vision. A similar episode had occurred after extreme exercise about 6 months before pregnancy. Otherwise her medical history gave negative findings. Her family history was significant in that her father and paternal grandmother had had parathyroid tumors.

At the time of admission the glucose level was 30 mg/dl. Subsequent fasting values were as low as 18 and 26 mg/dl with elevated serum insulin and C-peptide levels (15 μU/ml and 6.9 ng/ml, respectively). Serum calcium level was mildly elevated at 10.9 mg/dl. Serum cortisol, thyroid-stimulating hormone, and thyroid function tests all were normal. In spite of frequent feedings, repeated hypoglycemic reactions occurred necessitating 24-hour nursing surveillance at home. The hypoglycemic reactions that did not respond to oral feedings were treated with intravenous infusions of 50% glucose and/or glucagon injections.

Periodic ultrasonography of the fetus revealed normal growth and development. Nonstress testing and biophysical profiles were normal. Oxytocin induction of labor was carried out successfully at 41 weeks' gestation. The patient required continuous infusion of 10% glucose throughout labor and delivery to maintain normal serum glucose levels. A normal, 3033 gm female infant, with Apgar scores of 9 and 9, was delivered without complications. Computerized tomographic scanning of the head and abdomen with contrast post partum gave normal results. Pancreatic arteriogram (Fig. 1) with Hypaque revealed a 2 cm mass in the tail of the pancreas. At laparotomy a well-circumscribed mass was present in the distal one third

of the pancreas, and because of its location a splenectomy, as well as a partial pancreatectomy, was performed. Microscopic examination revealed large pancreatic islet cells confirming the diagnosis of an insulinoma. The serum calcium level during hospitalization was 10.9 mg/dl. The presence of an insulinoma, hypercalcemia, and a history of hyperparathyroidism in two relatives indicates that this is a case of multiple endocrine adenomatosis type I. There was no evidence of pituitary, bronchial, adrenal, or thyroid adenoma on clinical or laboratory examination.

Comment

The diagnosis of insulinoma is suggested by the clinical presentation of mental confusion, and loss of consciousness with profound hypoglycemia. Other conditions causing hypoglycemia, such as anterior pituitary failure, exogenous insulin administration, use of oral hypoglycemic agents, and renal failure, must be excluded. The diagnosis of an insulinoma will depend on demonstration of hypoglycemia with high insulin and C-peptide levels. Immunoreactive insulin/plasma glucose ratios >0.3 in particular support the diagnosis of an insulinoma.

Insulinoma in pregnancy is extremely rare, and we could identify only 13 reported cases. In these, symptoms began before, during, or immediately after delivery. In approximately half of the cases reported surgical exploration was done during pregnancy; the remainder were treated after delivery. Although invasive diagnostic procedures are relatively contraindicated during pregnancy, the severity of symptoms may dictate surgical intervention during the pregnancy.

Demonstration of the tumor may be difficult with sensitivities of the computerized tomographic scan, arteriography, and preoperative ultrasonography being 35%, 53%, and 59%, respectively. Approximately 10% of insulinomas are not detected by these methods, and surgical exploration may be enhanced by intraoperative ultrasonography, which is said to be 90% effective in localizing the tumor. In this case a mass was demonstrated by arteriography although the computerized tomographic scan failed to reveal the 2 to 2.5 cm. lesion in the tail of the pancreas.

There is some controversy over the effects of hypoglycemia on the fetus as there are reports of spontaneous abortions and embryopathy occurring before 10 weeks of pregnancy and also other reports that suggest that there are no effects on the long-term outcome of the neonate. Undoubtedly, as in this patient, repeated severe hypoglycemic reactions are emotionally stressful and the advisability of intervening surgically before delivery of the infant must be individualized.

Discussion

Dr. Charles R. Whitfield, Glasgow, Scotland. I would like to congratulate Dr. Smythe and his colleagues for presenting this rare case. These insulinomas occur only once in a population of a million so they must be very rare indeed in pregnancy. I also congratulate Dr. Smythe on finding 12 previous reports. In three of the case reports epilepsy was mentioned in

the differential diagnosis. A few patients also are first seen with confusional attacks or even coma caused by hypoglycemia. Only two patients had symptoms for the first time during pregnancy, and two became symptomatic after pregnancy.

Both the diagnosis and the location of these insulinomas are quite difficult. The sensitivities of the various diagnostic techniques are only 35% for computerized tomographic scanning, 53% for arteriography, and 59% for ultrasonography. I wonder why ultrasonography was not used in this case. Our radiologists would expect to detect all insulinomas by ultrasonography, except the rare case in which the pancreas is peppered with tiny microinsulinomas.

I think one of the most interesting things here is the absence of a deleterious effect on the fetus. Looking at the literature, there appears to be absolutely no fetal effect. The one case in which there was an unfortunate outcome of the pregnancy involved a woman who was seen for the first time at about 3 months' gestation with a diagnosis of missed abortion and the first symptoms of hypoglycemia. In all the other 11 pregnancies there was a successful outcome of the pregnancy.

Dr. E. O. Horger III, Charleston, South Carolina. We should note for all insulinomas, not just those in pregnant women, that >50% of them are found when they are <5 mm in diameter. To find a 5 mm tumor in a pancreas during pregnancy by ultrasonography would, I think, take a whale of a good ultrasonologist.

Dr. Robert Brame, Greensboro, North Carolina. I think it is interesting to consider what causes the symptoms in these cases. Tremor, tachycardia, and sweating in people who become hypoglycemic result from an outpouring of epinephrine. The dizziness, headache, visual disturbances, and mental problems are the products of hypoglycemia and a lack of energy in the brain.

I believe the diagnosis of insulinoma can be made in a case such as this. If the patient is not on a regimen of sulfonylurea and is not using exogenous insulin, there is not much else that will cause severe hypoglycemia with an extremely elevated insulin level. If the patient has hypoglycemia, hyperinsulinemia, and elevated C-peptide levels, that is virtually diagnostic of this disorder. At 16 weeks' gestation perhaps early surgical exploration should have been considered because the diagnosis presumably could have been established.

The diagnostic values of concurrent nonstress testing, amniotic fluid measurement, and Doppler velocimetry in screening a general high-risk population

Lawrence D. Devoe, MD, Paula Gardner, RN, Cheryl Dear, RN, and Ramon A. Castillo, MD

Augusta, Georgia

To determine the values of individual and combined biophysical fetal surveillance tests in a general high-risk population, we examined 1000 consecutive pregnancies complicated by either postdatism, hypertension, intrauterine growth retardation, or diabetes mellitus. Nonstress tests, amniotic fluid pocket measurements, and umbilical artery Doppler velocimetry were performed on each patient; each test was rated against gestational age–adjusted standards. Clinical end points included perinatal mortality, intrapartum fetal distress, 5-minute Apgar score <7, and neonatal acidosis in pregnancies without major anomalies or extreme prematurity (age at birth >32 weeks), delivered within 72 hours of final tests. Each testing method had specificity >90%. Sensitivities ranged from 69% (nonstress test) to 21% (Doppler velocimetry). Negative predictive values of each method exceeded 85%; positive predictive values ranged from 81% (nonstress test) to 42% (amniotic fluid measurements). The positive predictive value for *any* abnormal test was 54% and increased to 100% when *all* tests were abnormal; this latter condition occurred in only 2% of the total population. Amniotic fluid measurements or Doppler velocimetry, when compared with the nonstress test, appeared to be less powerful "stand-alone" screening tests. The performance of *all* tests in a single session confers little improvement in detection of fetal compromise if the nonstress test is normal; however, this approach may aid decision-making in the management of pregnancies when fetal maturity is not established. (Am J Obstet Gynecol 1990;163:1040-8.)

Key words: Pregnancy, risk screening, nonstress test, Doppler velocimetry, amniotic fluid volume

During the past two decades, a variety of noninvasive fetal assessment tests have evolved to detect possible intrauterine compromise: (1) the nonstress test (NST); (2) multiple parameter biophysical profile testing; (3) semiquantitative assessment of amniotic fluid volume; (4) Doppler velocimetry of umbilical arteries. The NST has become the most commonly used primary test for fetal well-being. It has been associated with high specificity but relatively low sensitivity. Its negative predictive value has been quite high, while its positive predictive value has been much lower.[1] Amniotic fluid volume assessment has been studied in selected conditions such as postdatism and intrauterine growth retardation (IUGR), but previous studies have been conflictual because of their use of different diagnostic criteria.[2, 3] Doppler velocimetry of the fetal umbilical arteries has shown promise in the evaluation of IUGR[4, 5] but its potential for screening unselected high-risk populations is undetermined.[6] While biophysical profile testing may yield better diagnostic performance values, when compared with the NST or amniotic fluid measurements alone,[7, 8] it is labor-intensive and time-consuming; for many clinicians it does not represent a practicable method for screening large populations. Prospective studies that directly compare individual testing methods in general high-risk populations have been limited[9] and have not clearly established the relative values of these approaches. The issue of screening capability is important as the different antepartum tests do not address the same aspects of intrauterine physiologic adaptation and impose different technologic requirements and costs.

We undertook the present study to examine the relative screening capabilities of the NST, amniotic fluid evalution, and Doppler velocimetry in a high-risk population typical of those commonly seen in antepartum testing centers. Using a uniform protocol in which all patients received each test in the same session, we sought to determine the individual and combined abilities of these methods to provide effective screening for intrauterine compromise. In so doing we hoped to establish a better understanding of the actual power of

these assessment tools so that improved antepartum management strategies might be developed.

Methods and materials

The study population consisted of 1000 patients, receiving care at the Obstetrics Clinic of the Medical College of Georgia, who were referred to the fetal assessment unit for well-being evaluation. The indications for testing included conditions that are considered to be risk factors for fetal-placental compromise: (1) postdatism, defined as pregnancy entering the forty-second week as corroborated by ultrasonographic dating before 24 weeks; (2) maternal hypertensive disorders, including chronic hypertension and preeclampsia; (3) insulin-requiring maternal diabetes mellitus; (4) IUGR, defined as fetal weight, estimated by sonographic mensuration, to be less than the 10th percentile for gestational age, according to our institutional birth weight standards. The distribution of testing indications is shown in Table I.

Fetal testing was performed between the gestational ages of 28 and 43 weeks, in accordance with an institutional protocol, and is further described for each method. For all tests study conditions were standardized for time of test (8 AM to 2 PM); maternal diet (2 hours postprandial), position (semi-recumbent), and activity (at rest for at least 1 hour); patients were instructed to refrain from smoking. All tests were performed by the same team of observers, using the same technical approaches.

The NST was conducted for a minimum of 30 minutes, with an electronic fetal heart rate (FHR) monitor in the Doppler mode, hard-wired to a microcomputer, driven by a previously described software program for archiving and analysis of baseline FHR.[10] A test result was considered normal if baseline rate, long-term variation, and incidence of accelerations and decelerations met institutional standards, adjusted for gestational age.[11] For the study group this meant that the mean baseline FHR was <155 or >120 beats/min, the coefficient of baseline FHR variation exceeded 0.02, at least three accelerations exceeding 15 beats/min amplitude and 15 seconds' duration were present, and no repetitive variable or late decelerations occurred. A test result was considered abnormal if two or more of these parameters fell >2 SD from the normal population means.

Amniotic fluid pocket evaluation consisted of determining the vertical and horizontal dimensions of the largest pocket visualized by real-time ultrasonography. Pocket measurements were related to gestational age standards[11]; a maximal pocket falling >2 SD below the normal mean was considered to represent reduced amniotic fluid volume. At all gestational ages the minimal dimensions of the largest visualized pocket should have exceeded 2 × 2 cm.

Doppler velocimetry was performed with a continuous wave probe, operating at 4 MHz, on an ultrasonographically localized midportion of umbilical cord. Studies were performed in the absence of fetal breathing and included at least 10 to 15 continuous cardiac cycles for the determination of mean systolic peaks and diastolic troughs to obtain a systolic/diastolic (S/D) ratio. Each velocimetry study consisted of three separate insonations, and these values were averaged to achieve a final S/D ratio. The S/D ratios were then rated against an institutional nomogram for gestational ages between 28 and 42 weeks. An abnormal value was considered to be either an S/D ratio exceeding the 90th percentile for gestational age or the observation of absent or reversed end-diastolic velocities. The cutoff for maximal S/D ratios varied with gestational age and showed a progressive decline from 28 through 42 weeks of gestational age. At 28 weeks the threshold for maximal S/D ratio was 4.15; at 32 weeks, 3.70; at 36 weeks, 3.50; at 42 weeks, 3.10.

Testing sessions were conducted at least weekly for pregnancies between 28 and 32 weeks and at least biweekly thereafter. Clinical management used test results to determine the need for subsequent interventions, according to the scheme shown in Fig. 1.

Obstetric outcomes for each pregnancy were examined for the presence of perinatal mortality, intrapartum fetal distress necessitating cesarean section or operative vaginal delivery, 5-minute Apgar score <7, and neonatal mixed or metabolic acidosis. Five-minute Apgar scores of <7 were considered only for infants when gestational age alone was not a confounding variable,

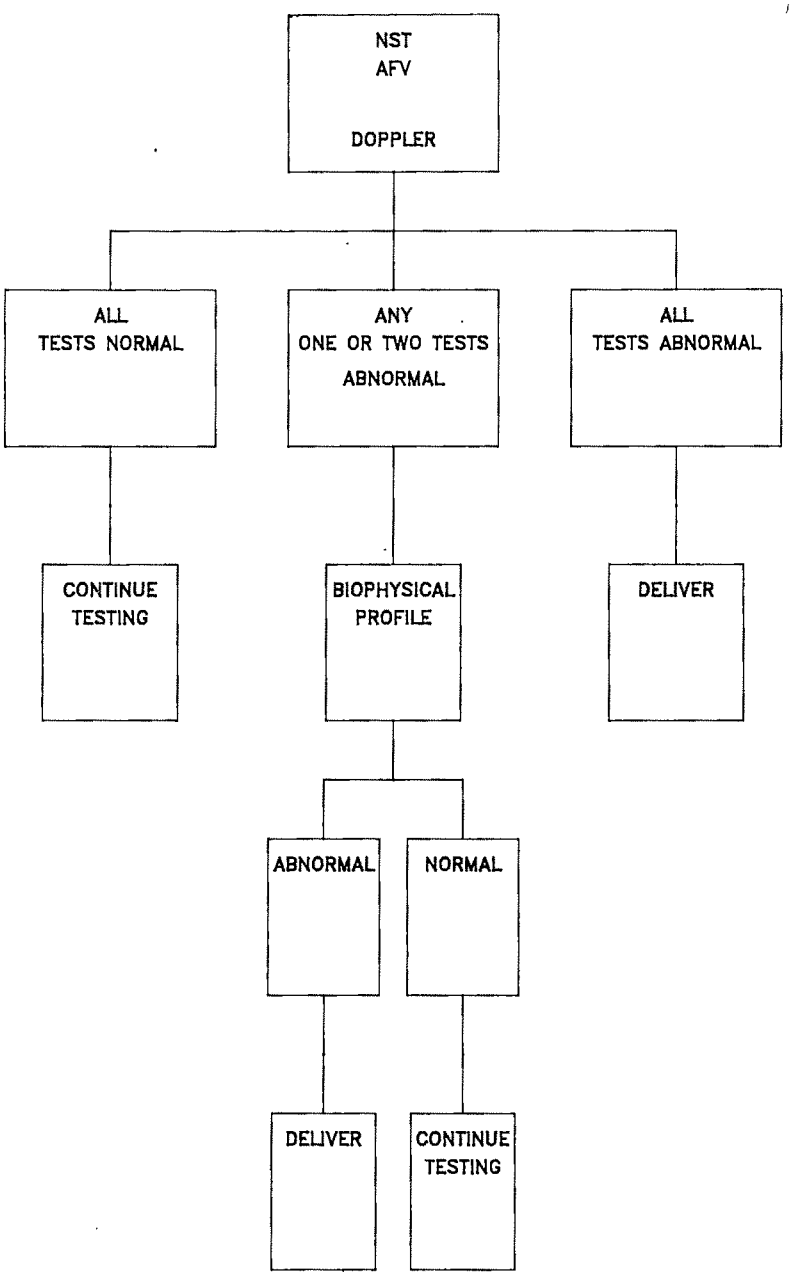

Fig. 1. Management of algorithm of antepartum testing used in study.

i.e., beyond 36 weeks. Neonatal acidosis was considered only when the umbilical arterial pH was <7.20 *and* the base excess exceeded −8.0 mEq/L.

Sensitivity, specificity, and positive and negative predictive values were determined for each test individually and in combination. Test sensitivities were rated against false-positive rates (1 − Specificity) with the use of receiver operating characteristic plots. Comparison between groups was performed by χ^2 tests, with a p value of <0.05 considered as significant.

Results

One thousand patients were evaluated according to the study protocol outlined in Methods and materials for the high-risk conditions listed in Table I; 26 patients were excluded from final statistical analysis because of the presence of significant anomalies detected at birth, multifetal gestations, confirmed gestational age <28 weeks at delivery, delivery outside the institution, or unavailability of umbilical cord blood gas values.

Obstetric outcomes of study group. One hundred

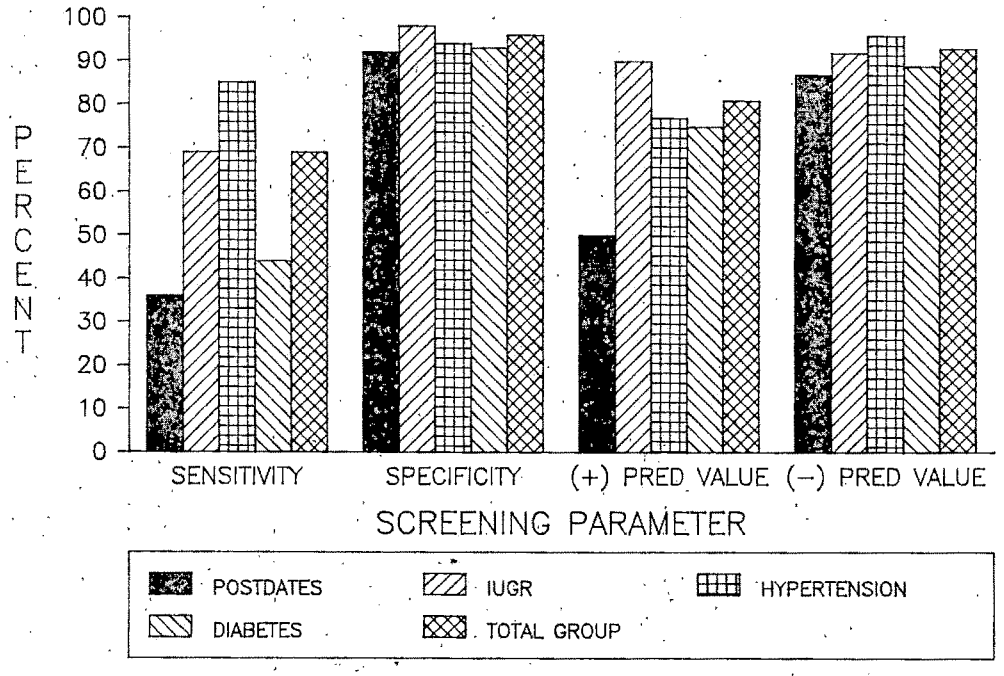

Fig. 2. Distribution of screening parameters associated with NST in study population.

eighty-eight fetuses or 19.3% of the total group had at least one of the previously described perinatal complications: antepartum death ($n = 1$); neonatal death ($n = 1$); intrapartum fetal distress ($n = 164$); 5-minute Apgar scores <7 ($n = 106$); neonatal acidosis ($n = 90$). The distribution of complicated outcomes, according to risk factors, is shown in Table I and was not significantly different among the individual risk groups. There were no perinatal deaths after normal antepartum tests. All patients were delivered of their infants at or beyond 32 weeks' gestational age. Mean (±SD) gestational age at delivery for fetuses in the IUGR, hypertension, and diabetes groups was 38 ± 1.2 weeks; mean (±SD) gestational age at delivery for the postdates group was 41.9 ± 0.3 weeks.

Test performance of study group. Figs. 2 to 4 show the screening performance of the final individual test results, obtained before delivery, for the total study group and the individual risk conditions surveyed. The mean (±SD) number of studies was 4.2 ± 2.2 for each patient in the IUGR, hypertension, and diabetes groups and 2.3 ± 1.2 in the postdates group. The 974 patients analyzed underwent a total of 3277 tests. The NST had the most frequent abnormal results (16.2%), followed by amniotic fluid assessment (10.6%) and Doppler velocimetry (8.2%). For any single test in the total study group the sensitivity was 78%; specificity, 85%, positive predictive value, 54%; and negative predictive value, 85%. Among the single assessment methods the NST had the highest sensitivity for the total study group and its individual risk categories; it also showed the highest positive predictive values for the entire study group (Fig. 2). There were significant differences among the individual risk groups for NST sensitivity, being highest in pregnancies complicated by hypertension (85%) and IUGR (69%). Similar trends were noted among the individual risk groups for NST positive predictive values (Fig. 2). Amniotic fluid assessment had lower sensitivity among all individual risk categories, ranging from 45% (hypertension) to 21% (postdatism); its positive predictive values were below 50% in all groups except for diabetes, in which it was 75% (Fig. 3). Doppler velocimetry had the poorest individual performance among all risk groups with a sensitivity ranging from 0% (postdatism) to 45% (hypertension); its positive predictive value fell below 50% in all risk groups except for hypertension (75%) (Fig. 4). Measures of individual test specificity and negative predictive values exceeded 80% in the total group and were not significantly different among the various risk categories.

Sensitivities, specificities, and predictive values for the test combinations in the total study group and all risk conditions are shown in Table II. The combined occurrences of all test results being abnormal had a positive predictive value of 100% and a false-positive rate of 0% but was observed in only 2% of the total study group. Receiver operating characteristic curves for individual tests and their combinations are shown

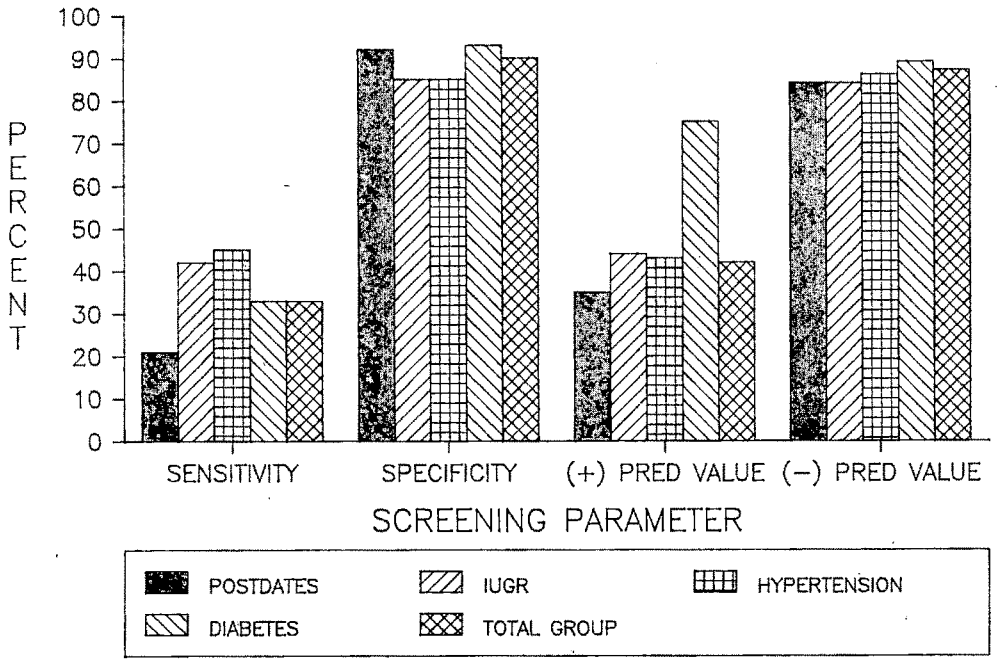

Fig. 3. Distribution of screening parameters associated with amniotic fluid assessment in study population.

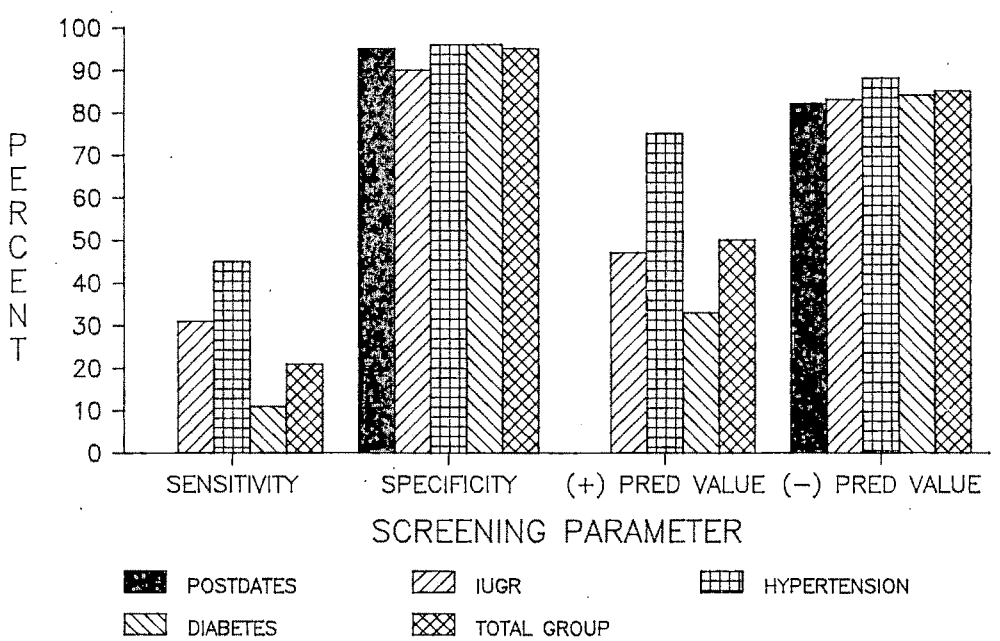

Fig. 4. Distribution of screening parameters associated with Doppler velocimetry in study population.

for the individual risk conditions in Fig. 5. This rating is based on the deviation of the plot from an ideal line passing through a false-positive rate of 0% (X axis) and sensitivity of 100% (Y axis). For the total study group and the individual risk categories the NST alone either equaled or exceeded the other individual tests or their combinations when rated in this fashion.

Comment

This study has examined the relative screening capabilities of antepartum tests that are commonly used to evaluate general and specific categories of fetal risk. Our goals were to determine whether any individual test or test combinations provided better screening performance in such a population and whether certain

modalities might be better suited for some risk conditions than for others. Prospective antepartum management was undertaken with the null hypothesis that each testing method was an equipotent screening tool. As no previous similar studies existed, there was no apparent reason to assume a priori superiority of a single testing approach. To provide further means of comparing test performances, each test was performed on all patients, proximate to their delivery, under a uniform study protocol. Test results were rated according to values derived from normal patients of comparable gestational ages. Finally, common objective pregnancy end points were chosen for evaluating all testing methods.

We found that the individual tests and their combination had similar abilities to detect fetuses who were at low risk for compromise, as judged by test specificity and negative predictive values, regardless of the antecedent risk factor that prompted antepartum evaluation. However, the NST appeared to be the most sensitive single test. Its positive predictive value equaled or exceeded that of amniotic fluid assessment or Doppler velocimetry in all risk conditions. This finding is consistent with what might have been anticipated from earlier studies of multiple parameter biophysical testing[7, 12] but differs from expectations generated by previous investigations that focused on amniotic fluid assessment[13] or Doppler velocimetry.[14, 15] These previous studies were performed on different obstetric populations, used different standards for test rating, and therefore cannot be considered directly comparable to the present investigation. Most past studies have also used arbitrary rating schemes for test assessment; these schemes are usually not related to normal gestational age standards and might not apply equally well to general high-risk populations, studied over a broad range of the third trimester. Further, the influences of test results on subsequent management were undoubtedly different for the other published studies; this may have introduced a bias that could either strengthen or weaken the apparent performance of a specific screening test.

We also found that individual or combined testing methods did not provide similar screening performance when evaluated in the context of individual risk conditions. This is illustrated by the higher sensitivities of the NST or amniotic fluid assessment for IUGR and hypertensive groups than for postdates or diabetic groups and the considerably higher sensitivities of Doppler velocimetry for these same risk conditions when compared with postdates pregnancies. These findings could reflect the different causes of fetal compromise that these risk conditions engender rather than the prevalence of fetal compromise itself, which was similar for all individual risk conditions.

While it might appear that individual methods, notably, the NST, were superior screening tools for our population, it should be recognized that positive predictive errors also were highest when only single testing methods were considered. Approaches that combined the NST with either Doppler velocimetry or amniotic fluid assessment decreased this type of error to nearly 0%. This becomes an important consideration when testing is performed before the establishment of fetal maturity and when only one of the testing methods yields an abnormal result.

The potential cost-effectiveness of screening approaches is difficult to assess since the costs for patient testing may vary widely among institutions. In this particular study the cost of the NST was $75 per test and amniotic fluid evaluation added $25 to this figure. As this investigation began before Food and Drug Administration approval of Doppler velocimetry for clinical

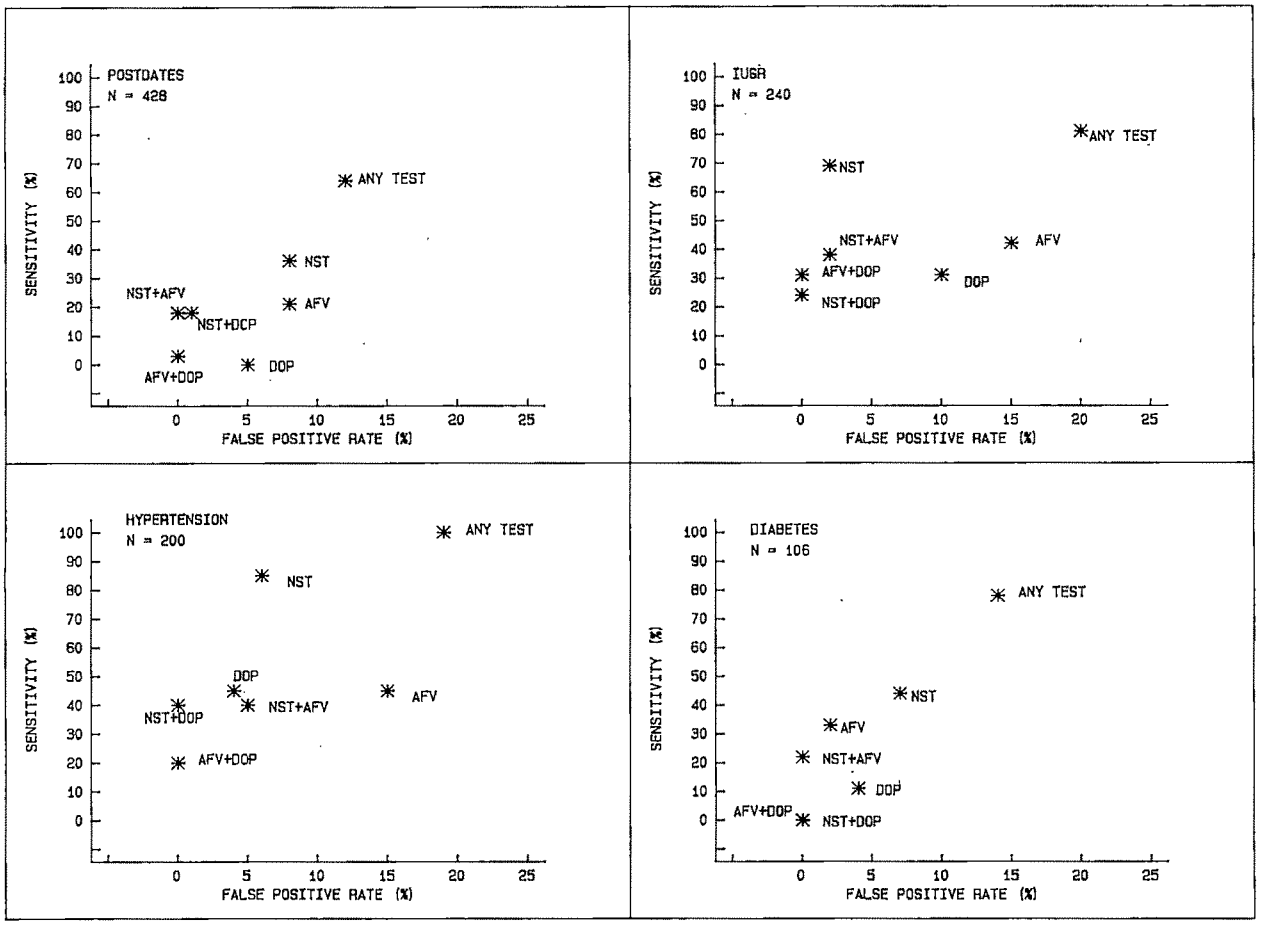

Fig. 5. Receiver operating characteristic plots for all tests in each risk category. Values for each test are labeled in plots according to individual or combined tests. *AFV*, Amniotic fluid assessment; *DOP*, Doppler velocimetry.

application, this latter test was not considered for patient billing; Doppler velocimetry charges are currently an additional $25 per test. On the basis of the 3277 tests performed in the entire group, the cost per patient would have averaged $330, as compared with a mean daily cost of hospitalization for a normal vaginal delivery of more than $500, excluding charges for labor and delivery care. The cost of a single day of neonatal intensive care (which might have been avoided by timely intervention) during the time of the study averaged $1500 in our hospital; the average length of admission to the neonatal intensive care unit for sick infants older than 32 weeks was approximately 14 days, if for reasons other than prematurity. The overall cost of this testing program, approximately $410,000, would be counterbalanced by preventing 20 neonatal intensive care admissions. Finally, the perinatal death rate associated with this approach was 2.1 per 1000 or approximately one third of that noted in our institution for nonanomalous infants delivered at or beyond 32 weeks' gestational age, during this time period.

We may draw the following conclusions from this study. First, in all risk conditions examined, the NST was superior to the other testing methods when viewed as an individual test. As a corollary, neither amniotic fluid assessment or Doppler velocimetry should be considered as an adequate, "stand-alone" antepartum screening method. Second, the screening power of any individual test varies with risk condition. In particular, it would appear that no individual or combined testing method is a very sensitive screening tool for pregnancy complicated by postdatism or diabetes mellitus and that the occurrence of these risk factors might be better served by other testing techniques, such as multiple parameter biophysical testing or contraction stress testing. This issue merits future prospective evaluation. Third, combinations of these screening tools, performed at the same session, may improve the accuracy of prediction of fetal compromise and should be strongly considered when the fetal maturity is not established. Finally, the development of objective, age-related reference standards and the accumulation of

substantial clinical experience with the antepartum evaluation of specific risk entities should be undertaken in all testing centers that assess large numbers of high-risk pregnancies. This would enable better contextual evaluation of the antepartum tests used in screening high-risk pregnancies and could lead to more appropriate bases for clinical decision-making.

Discussion

Dr. Karen L. Ferguson, Palm Bay, Florida (Official Guest). Antepartum identification of the fetus at risk for preventable morbidity or mortality remains the major challenge of modern obstetrics. An optimal test method would assess fetal status and ultimately reduce prenatal morbidity and mortality. The testing process must be cost-effective, accurate, sensitive enough to detect pregnancies at risk, and specific enough to identify pregnancies that will have a good outcome.

Methods for determining fetal risk that are currently in use have a high false-positive rate. False-positive results encourage unnecessary obstetric intervention and increase the risk of maternal and fetal morbidity. Establishing safe parameters for intervention is the hallmark of a meaningful study protocol.

The study presented has several strengths. The study design is prospective. The number of subjects is large enough to allow analysis of the collected data. Additionally, the authors have made an effort to control extraneous variables. The tests were standardized for time of day, postprandial state, maternal position, activity, and avoidance of smoking. Unfortunately, the study used birth weight standards that were based on institutional norms that were not described in the paper. It is impossible to compare the results with previously published studies. In addition, an institutional nomogram was used to determine abnormal ratios of systolic/diastolic pressure. In addition, amniotic fluid pocket evaluations were based on institutionally developed norms that were not described in the article. Since amniotic fluid pocket norms were not given, comparison of the authors' results with those published by other institutions cannot be made.

Although the study design of this article is commonly used, it is fundamentally flawed. The study does not address the central issue of the usefulness of antepartum tests in preventing an adverse neonatal outcome. An adequately designed study would be unethical and would not be feasible. An adequate study would prospectively and randomly assign patients to the three tests used and then allow the pregnancies to follow their natural course without intervention. Clinicians in this study group, however, were advised of test results and subjectively altered the clinical outcome by altering their plan of care. Clinical intervention guided by a false-positive test result could inappropriately alter a patient's clinical course. The authors of this article did not present data describing the frequency of type of intervention, such as induction of labor or cesarean section, when a test result was abnormal.

This study suggests that a poor outcome can result in spite of physician intervention in response to abnormal test results. One would have to question the value of prognostic or screening tests that will not alter fetal risk. Considering the overwhelming ethical and philosophical constraints, the authors should be congratulated on their study design.

Although the authors did not include a physiologic discussion of the superiority of the NST as a screening tool, this article does bring into focus the important issue of the multifactorial etiology of fetal compromise. Since a variety of disease states can complicate pregnancy and cause intrauterine compromise, it is logical

to carefully examine and compare a combination of methods of fetal surveillance, with measurement of different aspects of maternal-fetal physiologic parameters. It is only through carefully executed studies such as this one, which examine physiologic responses in each high-risk disorder, that the clinician is ultimately guided to choose the proper combination of antepartum tests and to evaluate and act on intrauterine compromise.

Dr. Ronald V. Wade, Charlotte, North Carolina. I would like to congratulate Dr. Devoe on a very nice article and applaud him on 1000 cases reviewed. I understand the magnitude of that effort. Two quick questions: Since a lot of the abnormal outcomes were classified as "fetal distress," would you elaborate on what those were? Were they fetal monitoring data or otherwise? Second, do you have a breakdown of the sensitivity, specificity, and predictive values that are based only on the outcome variable of cord pH?

Dr. Salih Yasin, Miami, Florida. I appreciate the rich article with all the information. We are still looking for the ideal test. People who are in monitoring probably would admit that there is no ideal test. The reason for this is that we always expect babies to behave in a mathematical fashion, which is not how they behave. There are still biologic entities that behave differently with different situations. We do not find in the data presented any statement of the influence of the maternal condition on intervention. Ultimately, with all the testing, it is really the maternal-fetal unit that determines part of the outcome.

Dr. Robert Bowden, Lynchburg, Virginia. I would like to know if Dr. Devoe would share with us any data on the 26 patients he excluded because of fetal abnormality.

Dr. Devoe (Closing). Perhaps what I should do first is address the point made in the discussion about standards. Most of our biophysical standards that we used in the study have been previously published and are referenced in the article itself. Second, we have found, in looking at amniotic fluid volume, Doppler velocimetry, and birth weight, that if you take any one of these three parameters to various institutions you find that the populations are not particularly continuous or overlapping. I would recommend that those interested in using such reference points probably ought to develop their own standards and base their discrimination on their own population rather than adopting that developed by somebody else, working with perhaps a significantly different group of patients.

Dr. Wade raised an issue regarding abnormal outcomes of fetal distress. Fetal distress was defined in most cases by a combination of fetal heart rate patterns (changes such as persistent late decelerations, loss of beat-to-beat variability, sustained tachycardia or bradycardia, or severe variable decelerations). All instances were corroborated by scalp pH. As far as breaking these down into cord pH alone for fetal acidosis, I don't have the data but they are available.

Dr. Yasin's points are very well taken. I think the issue here was not so much to define an ideal test but rather to take more of a real-world view and try to sort out the very confusing situation of how one addresses the multiplicity of tests available and to pick what might represent the most reasonable screening methods available. We must recognize that they may all have flaws but all of these methods have been championed to some extent to the exclusion of other methods. What we really tried to do was to put some balance back into an unbalanced situation. I think that was the main thrust of this particular study, and we knew before we started that it was unlikely we were going to find a method that was unerring and perfect. This would have been a remarkable accomplishment for anybody.

The final question dealt with the patients who were excluded. I do have data for these patients in our files, but the reasons that most of them were excluded was that their good or bad outcomes were due to problems that would not necessarily have been pertinent to the testing method or they were delivered outside our facility and data collection was not done in the same way as it was done for all the other patients. The cord blood gas values were unavailable in such circumstances so we could not evaluate our end point of neonatal acidosis. That is the main reason why they were not included.

Eclampsia

VI. Maternal-perinatal outcome in 254 consecutive cases

Baha M. Sibai, MD
Memphis, Tennessee

During a 12-year period, 254 cases of eclampsia were managed at this center. Eighty patients (32%) did not have edema, 58 (23%) had "relative hypertension," and 49 (19%) did not have proteinuria at the time of convulsions. Eclampsia developed at ≤20 weeks in 6 patients and beyond 48 hours post partum in 40 (16%). Convulsions developed in 33 while they were receiving standard doses of magnesium sulfate for preeclampsia during or after birth, and subsequent seizures developed in 36 (14%) after magnesium sulfate therapy was started. There was one maternal death (0.4%) and morbidity was frequent (acute renal failure, 4.7%; pulmonary edema, 4.3%; cardiorespiratory arrest, 3.1%; and aspiration, 2%. The use of multiple drug therapy was associated with significant maternal and neonatal complications. The total perinatal mortality was 11.8%, with the majority of them related to either abruptio placentae or extreme prematurity. These findings emphasize the need for intensive monitoring of women with preeclampsia throughout hospitalization and underscore the importance of maternal stabilization before and during transfer. (Am J Obstet Gynecol 1990;163:1049-55.)

Key words: Eclampsia, complications, perinatal outcome, maternal transfer

Eclampsia is defined as the onset of convulsions or coma during pregnancy or post partum in a patient who has signs and symptoms of preeclampsia. According to Chesley,[1] a description of this syndrome was mentioned in the ancient writings of both the Egyptians and the Chinese. In recent years the reported incidence of eclampsia ranged from 1 in 110 to 1 in 3448 pregnancies.[2-4] The extremely low incidence reported from Sweden indicates that appropriate prenatal care and early hospitalization of patients with preeclampsia will prevent most cases of eclampsia.[3] Similar findings were reported by Zuspan,[5] as well as by Gilstrap et al.[6] The latter study demonstrated that eclampsia was rarely encountered in patients with proper management who had early and prolonged hospitalization for mild pregnancy-induced hypertension. The study included a total of 545 women who were hospitalized at 25 to 38 weeks' gestation. The duration of hospitalization ranged from 2 to 120 days (average 24 days) with only one patient (0.2%) having eclampsia.

Eclampsia is a life-threatening emergency that continues to be a major cause of serious maternal morbidity and is still the leading cause of maternal mortality worldwide. Complicated cases and mismanaged cases are responsible for most maternal deaths, which are usually due to intracerebral hemorrhage, pulmonary edema, or renal, hepatic, or respiratory failure.[4] In addition, its presence is usually associated with high perinatal mortality and morbidity. The main causes of perinatal mortality and neonatal morbidity from eclampsia are preterm delivery, fetal growth retardation, and abruptio placentae.[4]

At this institution, which is a tertiary referral center for five states, the incidence has remained at about 1 in 320 deliveries for the past 30 years. The factors responsible for this high incidence have been the subject of a recent report from this institution.[7]

During the past 12 years, 254 cases of eclampsia were managed at this perinatal center. The purpose of this study is to evaluate the clinical course and outcome in these patients with emphasis on the pitfalls in the diagnosis and management of eclampsia.

Material and methods

From Aug. 1, 1977, to April 30, 1989, 254 consecutive cases of eclampsia were managed at E. H. Crump Women's Hospital and Perinatal Center, Memphis. The study population and methods used have been described previously.[7-10] Patients with other causes of convulsions were excluded. All patients with atypical onset of eclampsia had a special neurologic evaluation to rule out the presence of neurologic causes of seizures as

described in a previous report.[10] During the time period of this study, our basic management plan of eclampsia remained the same except for certain changes to improve on our basic protocol. The regimen of intravenous magnesium sulfate was changed to increase the serum magnesium levels achieved during therapy. The current regimen consists of a 6 gm loading dose infused over 20 minutes, followed by a maintenance dose of 2 gm/hr. The administration of hydralazine by a continuous infusion method is no longer used because of the high incidence of fetal distress associated with that therapy. The current treatment of severe hypertension consists of the use of either bolus injections of 5 to 10 mg of hydralazine or bolus injections of 20 to 40 mg of labetalol. In January 1985 an obstetric intensive care unit was established at this hospital, and since then all cases of complicated eclampsia have been managed in this unit.

Results

During the study period there were 254 patients with eclampsia among 83,720 deliveries (1/330 deliveries). One hundred six (40%) of these patients had prenatal care at our clinics and 148 (60%) either were maternal transfers or had no prenatal care. Two hundred (79%) were black, 53 (21%) were white, and one was Asian. This racial distribution is similar to that of the general obstetric population at the Perinatal Center. The mean age was 18.5 years (range, 11 to 36 years), but 221 (87%) were younger than 25 years.

Table I summarizes the clinical findings in these patients at the time of convulsions. It is important to note that the classic triad used to diagnose preeclampsia either was absent or the symptoms were mildly abnormal in about 20% of these patients. In addition, ≤50% of the patients had either severe hypertension or significant proteinuria at time of convulsions. One hundred twenty-two patients (48%) had eclamptic convulsions while they were under medical supervision in a hospital. Ten of these patients had convulsions after hospitalization for mild preeclampsia despite good response, and an additional 20 patients had convulsions while being evaluated for preeclampsia in an admission area. Evaluations were being carried out in various local hospitals and in our hospital for possible admission of the patients. These patients were having repeat evaluation of blood pressure or urine protein testing. The mean time that the patients were in the unit during evaluation was 72 minutes. The remaining 92 patients who had convulsions during hospitalization did so for the following reasons: while receiving standard magnesium sulfate therapy, during the postpartum period (late onset), while receiving other anticonvulsive prophylaxis, or after failure to institute appropriate antiprophylaxis therapy either during or immediately after birth.

Table II summarizes the gestational ages at the time of convulsions. Fourteen patients (5.6%) had eclampsia during the midtrimester, and in six of them eclampsia developed before 21 weeks' gestation. Five of the 14 patients had essential chronic hypertension, but none of them had connective tissue or renal disease. In addition, none of the 14 had evidence of renal disease on subsequent follow-up.

The onset of convulsions occurred before delivery in 181 patients (71%) and after delivery in 73 (29%). Forty (55%) of the 73 patients with postpartum eclampsia developed convulsions ≥3 days after delivery (range, 3 to 22 days). Twenty-two of these patients had preeclampsia before delivery, during labor, or post partum. They received intravenous magnesium sulfate during labor and for a minimum of 24 hours post partum. There was clinical evidence of improvement in the preeclamptic process in all 22, yet convulsions developed either during hospitalization or a few days after discharge. The other 18 patients were normotensive during pregnancy and had normal postpartum blood pressures. They had sudden onset of severe preeclampsia or convulsions at home and then were readmitted to the hospital. Headaches, visual disturbances, or both of 1 to 4 days' duration were reported by all patients before the onset of convulsions. None of these patients had a history of seizure disorder, and no patient had neurologic deficits or seizures on follow-up.

Thirty-three patients (13%) had convulsions while receiving standard doses of magnesium sulfate for intrapartum or postpartum treatment of preeclampsia. Four patients were receiving the standard intramuscular regimen recommended by Pritchard et al.,[11] one patient was receiving intermittent bolus injections of magnesium sulfate, and 28 were receiving the continuous intravenous regimen. In addition, 36 (14.2%) of the 254 women with eclampsia had one or more convulsions after institution of magnesium sulfate. Thirty of the 36 remained free of seizures after an additional 2 to 4 gm intravenous bolus of magnesium sulfate, three responded to a short-acting barbiturate, one required an intravenous Pentothal drip, and two required muscular paralysis with intubation to control further seizures.

Thirty-two patients (13%) had convulsions while receiving multiple drug therapy to treat preeclampsia before, during, or after birth. The drugs used were diuretics, various antihypertensives, analgesics, sedatives, and anticonvulsants (phenobarbital, diazepam, phenytoin). These drugs were used either orally, intramuscularly, or intravenously. In addition, 12 of the women with eclampsia had further seizures after receiving various doses of phenobarbital, diazepam, or phenytoin. It is important to note that four of seven patients with eclampsia who were treated with large doses of phenytoin had subsequent convulsions within

4 hours of receiving phenytoin. The clinical characteristics of these 32 patients were not different from those of the other patients. The majority of them were managed at local hospitals and the medications were prescribed by their physicians or by consulting physicians (internists or neurologists). Serum phenobarbital levels were not available in patients receiving such therapy; however, all four patients with recurring seizures after administration of phenytoin had adequate serum phenytoin levels. All five patients with aspiration in this study and six of the eight with cardiorespiratory arrest received a combination of these medications. Moreover, several women in this group were delivered of babies who had significant neonatal morbidity (respiratory depression, apnea, shock, acidosis, hypotonia, and low Apgar scores).

Perinatal outcome. The 254 pregnancies resulted in 263 births (nine sets of twins). There were 16 stillbirths and 15 neonatal deaths for a total perinatal mortality of 11.8%. It is important to emphasize that in 21 of the 31 cases of perinatal death the infants had a birth weight <1000 gm with 10 being <500 gm. In addition, two of the stillbirths were due to congenital anomalies and three neonatal deaths were due to congenital infections. Overall, the presence of abruptio placentae was associated with 12 of the 31 perinatal deaths.

One hundred twenty-four (49%) women had cesarean sections for various reasons. The most frequent indications were fetal distress, fetal growth retardation, abruptio placentae, extreme prematurity with unfavorable cervix, and failed induction of labor.

Maternal outcome. There was one maternal death (0.4%) in a patient with antepartum eclampsia at 39 weeks' gestation who was admitted in a moribund state. The patient had severe preeclampsia (blood pressure 220/140 mm Hg, 4+ proteinuria), yet she was transported in a private car and had several convulsions resulting in cardiac arrest at the time of arrival to the perinatal center. She was resuscitated and underwent cesarean section for management of fetal distress with delivery of a live term infant with good Apgar scores. The patient was comatose on admission and had a "silent" electroencephalogram immediately post partum that persisted until death 9 weeks later. Table III summarizes significant maternal complications in these patients. The incidence of abruptio placentae was 9.8%, but most of these complications occurred in patients with eclampsia before delivery. The incidence of the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets) was also 9.8%, which was similar to the incidence seen in severe preeclampsia at our hospital.

Eleven of the 12 patients with acute renal failure had reversible acute tubular necrosis with six requiring dialysis. The average number of dialysis procedures per patient was 1.9 (range 1 to 4) and the average duration of oliguria-anuria was 4.6 days. All 11 patients had normal renal function on follow-up, including the patient who died (serum creatinine 0.5 mg/dl before death). The other patient had renal disease with significant renal impairment before pregnancy and required dialysis several months post partum. All 11 patients with pulmonary edema had multiple obstetric, medical, and, surgical complications requiring various therapeutic interventions.

A summary of all neurologic abnormalities is presented in Table IV. Except for the patient who died of diffuse cerebral encephalopathy, all neurologic abnormalities were transient without any residual deficit. Most of them were due to either cerebral edema, vasospasm, or infarcts. None of the patients had evidence of intracerebral hemorrhage. In addition, none of the surviving women had evidence of neurologic deficit or seizures on follow-up.

Table I. Clinical findings ($N = 254$)

	No.	*%*

37-41	115	45.2	40

Comment

The findings of this study support our previous observation that the incidence of eclampsia in this hospital has not changed during the past 30 years.[7] This high incidence reflects the nature of the perinatal center that serves as the main referral center for many hospitals in five different states in the region. If one considers

Table III. Maternal complications ($N = 254$)

	Total cases		*No. delivered by cesarean section*
	No.	*%*	
HELLP syndrome*	25	9.8	20
Abruptio placentae	25	9.8	19
DIC†	13	5.1	9
Acute renal failure	12	4.7	9

Cerebral death	1	0.4
Intracerebral hemorrhage	0	0

the number of deliveries in the region and assumes that all women with eclampsia are referred to this center, the incidence of eclampsia for the whole region is about 1 in 1600 deliveries. This incidence is consistent with the national average and is similar to the respective incidence in the developed countries.

It is generally accepted that pregnancy-induced hypertension has an insidious onset with hypertension appearing relatively late in its course. The hypertension may be absolute (≥140/90 mm Hg on two separate occasions, at least 6 hours apart) or relative in the form of a threshold increase in either systolic or diastolic blood pressure. The diagnosis of preeclampsia requires the presence of hypertension with either edema, proteinuria, or both. It is also suggested that the clinical course in the development of eclampsia is characterized by a chronic, gradual process that begins with progressive weight gain followed by hypertension and proteinuria and ends with the onset of generalized convulsions or coma. The findings of this study reveal that a large percentage of patients with eclampsia lacked one or more of these clinical findings at onset of convulsions. In fact, 23% had minimal to absent hypertension, 19% did not have proteinuria, and 32% did not have edema. Overall, about 20% of these patients did not have the classic triad of edema, proteinuria, and hypertension. In addition, about one third of the women who had regular and appropriate prenatal care had abrupt onset of either severe preeclampsia or eclampsia.[7] None of these patients had any evidence of abnormal weight gain, edema, proteinuria, or changes in blood pressure. This finding is similar to that reported from Sweden by Moller and Lindmark[3] and to that reported from Scotland by Campbell and Templeton.[12]

There are several other clinical changes that might serve as warning symptoms before the onset of convulsions. These include severe and persistent headache, blurred vision, photophobia, irritability, transient mental changes, epigastric or right upper-quadrant pain, nausea, and vomiting. Some of these changes may be subtle, especially in the absence of significant hypertension or proteinuria, and may be missed by the nurse or physician during routine prenatal visits. Thus it is important that all health professionals taking care of pregnant women be familiar with the clinical changes that might herald the onset of convulsions. It is my opinion that all obstetric patients should be instructed to report the above changes immediately. In addition, these patients should be evaluated as soon as possible with prompt hospitalization of all patients with diagnosed preeclampsia. If the patient becomes normotensive in the absence of proteinuria and other premonitory symptoms, outpatient observation can be considered in a select group of patients. This form of ambulatory management is appropriate in reliable patients only during the early stages of the disease when the fetus is immature. These patients should be instructed to be at bed rest at home and to have frequent evaluation of blood pressure and urine dipstick measurements of protein. In addition, they should be evaluated by a physician at least twice a week.

Eclamptic convulsions may develop at home, at prenatal clinics, during maternal transport, during evaluation for preeclampsia before hospitalization, or during hospitalization for preeclampsia. It is disturbing to note that 48% of the women in this study had convulsions while under medical and nursing supervision. In some of these latter patients convulsions developed in the evaluation area during repeat measurements in cases of mild hypertension for establishing the diagnosis of preeclampsia or before admission to the labor and delivery area. One such patient developed a stormy course that was complicated by coma as a result of massive cerebral edema and by acute renal failure, liver failure, disseminated intravascular coagulopathy, and pulmonary edema. Fortunately, both mother and baby survived without any residual deficit. This finding underscores the importance of immediate hospitalization and prompt institution of magnesium sulfate therapy in patients presenting with any of the prodromal symptoms mentioned previously irrespective of the level of hypertension.

In several patients convulsions developed after hospitalization for preeclampsia. In some of them ante-

partum convulsions developed during conservative management of preeclampsia remote from term. These patients had convulsions despite being normotensive after hospitalization or while receiving various antihypertensive drugs and/or anticonvulsive oral medications. This finding is in disagreement with the recommendation that treatment of maternal blood pressure in preeclampsia will prevent eclamptic convulsions.[12] In addition, the use of oral anticonvulsive drugs such as diazepam, phenobarbital, or phenytoin in patients with preeclampsia does not prevent eclamptic convulsions and might give the clinician a false sense of security.

Seventy-nine patients (31%) had atypical onset of convulsions. In 33 convulsions developed while they were receiving standard regimens of magnesium sulfate; they developed in six at ≤20 weeks' gestation and in 40 at ≥3 days post partum. It is important to note that each of the 18 patients with normotensive gestations who experienced late-onset postpartum eclampsia had premonitory findings (headache or visual symptoms). In addition, 36 (14%) of the patients with eclampsia had subsequent seizures after receiving magnesium sulfate. Furthermore, several patients had subsequent seizures after receiving various other traditional anticonvulsive medications. These findings emphasize the need for close monitoring of all women with preeclampsia and eclampsia during labor and throughout the postpartum period. It is important to note that magnesium sulfate ultimately controlled eclamptic convulsions in 248 (98%) of the 254 women with eclampsia. Thus magnesium sulfate should remain the drug of choice to prevent and treat eclamptic convulsions.

Many obstetric units have little or no experience regarding the management of eclampsia. Consequently, most physicians are referring such patients, especially complicated cases and those remote from term, to tertiary care centers. Thus it is recommended that physicians and nurses referring such patients should consult with physicians at the perinatal center before transport, the patient should be stabilized regarding blood pressure and control of convulsions before transport, and the patient should be sent in an ambulance with medical personnel in attendance.

Pregnancies complicated by eclampsia are associated with poor maternal and perinatal outcomes. The reported maternal mortality ranges from 0.4% to 14% depending on the experience and facilities of the reporting center, as well as on the condition of the patient on admission to the center. Pritchard et al.[11] reported one maternal death among 245 women with eclampsia treated with a standardized protocol from 1955 to 1983. In addition, maternal morbidity was infrequent, and none of the patients had intracerebral hemorrhage. This excellent maternal outcome is attributed to the experience of the physicians managing these patients, the use of a standardized protocol for eclampsia, and the availability of appropriate intensive care facilities. In contrast, Lopez-Llera[14] reported 98 maternal deaths (13.9%) among 704 cases of eclampsia managed in Mexico, while Adetoro[15] reported 94 maternal deaths (14.4%) among 651 cases of eclampsia managed in Nigeria. However, it is important to note that many patients in these studies were admitted in a moribund state with multiple complications including intracerebral hemorrhage and cardiorespiratory, liver, and renal failure. There was one maternal death in this study that could have been prevented by proper maternal transport. In addition, many other patients had life-threatening complications caused by errors in management before and during transport. However, almost all of these patients survived without residual damage after arrival to the perinatal center. This finding emphasizes the importance of early and proper referral of such patients to centers with appropriate maternal and neonatal care facilities.

In summary, maternal mortality and morbidity in eclampsia are principally associated with complicated cases. Recent advances in both obstetric and neonatal intensive care have resulted in significant improvement in maternal and perinatal outcome of these pregnancies. Perinatal mortality and morbidity are mainly associated with abruptio placentae and eclampsia remote from term, especially in the midtrimester. At present, patients with these complications should be referred to a tertiary care center with the experience and facilities to manage critical maternal complications and provide intensive care for the immature infant.

Discussion

Dr. Thomas M. Stubbs, Charleston, South Carolina (Official Guest). The disease eclampsia continues to threaten our patients, even as we enter the last decade of the twentieth century. In this large report of 254 cases, the sixth of a series, Dr. Sibai has shown five things of particular importance. First, we must beware of this disease, even in patients who lack either abnormal edema or abnormal proteinuria. Second, great caution is required in the presence of central nervous system symptoms, even when other findings indicate only mild disease. Third, magnesium sulfate continues to be associated with the best outcomes. Fourth, transport of the patient is a dangerous time. Fifth, good communications are important if there is a change of physicians. There are some differences in our management of these patients at the Medical University of South Carolina. We have had success with a continuous intravenous infusion of hydralazine for the control of severe hypertension. Whether one gives this drug as a series of small intravenous boluses, as is done in Memphis, or as a continuous intravenous infusion, as is done in Charleston, the pitfall for the physician is the same. That pitfall is the fact that the drug doesn't reach its peak effect until 20 minutes after administration. Thus overzealous dosing can result in a greater fall in blood pressure than was originally intended. Also, stress headaches are common in our patients, including those who go on to have preeclampsia. The physician at the bedside must use clinical judgment in deciding whether a particular headache is a signal for magnesium sulfate therapy. Nonetheless, these data do show convincingly that the physician should consider a headache a major threat in a patient with preeclampsia. The low incidence of maternal complications in this report is remarkable. Six years ago, Dr. Jack Pritchard published a series of 245 cases of eclampsia with only a single maternal death and no maternal intracranial hemorrhages; these maternal outcomes are identical to those presented here. Dr. Sibai has shown again that in the most experienced hands only an occasional maternal death will occur. Even so, this article reports no decrease in the incidence of eclampsia over the past 30 years at Dr. Sibai's institution. As we look to the future and as we look for a way to improve outcomes, the perils of maternal transport require our attention. Perhaps the most important finding in this article is that remaining maternal morbidity and mortality are so frequently linked to this transport problem. Dr. Sibai, how do you advise your colleagues in the Mississippi Valley regarding transport of patients with preeclampsia and eclampsia, including type of vehicle, accompanying personnel, drug choice, and route of drug administration? Also, do a patient's reflexes or a great distance from the hospital affect your advice regarding magnesium sulfate?

Dr. Hugh Randall, Atlanta, Georgia. I can't tell you how much I enjoyed the article. It is always an enlightening event when Dr. Sibai presents the great work that he has done in hypertension. We have seen a number of complications occurring when the patient goes for imaging, either computerized tomographic imaging or magnetic resonance imaging, particularly when the patient goes directly from the intensive care unit to the radiology department. Dr. Sibai, what type of monitoring would you recommend when patients undergo imaging and at what stage of the disease would you recommend that imaging be done?

Dr. Sibai (Closing). I thank Dr. Stubbs for his comments. I guess the key issue is maternal transport. It has been a problem, and it continues to be a problem. Actually 2 weeks ago we had new memos and letters handed down to all physicians and nurses in the region suggesting to them the proper way to send these patients. It makes sense that when someone refers a patient to you he will call. We still have physicians and nurses who will send patients to us without even telling us the patient is on her way. At the present time, when a physician or nurse calls us, the first thing we tell them is that it is their responsibility to stabilize the patient before sending her. Some patients have a long way to go. If the patient is seriously sick, the referring doctor must take care of her even if she is in a local level I or level II hospital. We recommend that every patient receive magnesium sulfate irrespective of the severity of the disease. We recommend the use of 4 gm of magnesium sulfate intravenously plus 10 gm intramuscularly. If physicians don't like to use intramuscular magnesium sulfate, we recommend to them that they give a 6 gm intravenous loading dose plus 4 gm intravenous magnesium sulfate in 250 ml of fluid to be administered

over 2 hours. If this 4 gm is injected rapidly, it will not be toxic to the patient because the total will be 10 gm, which is safe for any patient who is pregnant. If the patient has severe hypertension, we recommend to the physician that they should control the blood pressure of the patient before sending her. The patient should be sent in an ambulance because, despite the intravenous magnesium sulfate, patients can still have convulsions. More important, we tell them to send an accompanying physician or nurse capable of handling her problems.

In regard to Dr. Randall's comments regarding computerized tomographic scans and magnetic resonance imaging, I have been doing them for research purposes. Some patients will lapse into coma, and some have more complicated cases of eclampsia, especially those that develop >3 days after delivery. In these cases the presence of other neurologic problems must be ruled out, and we would recommend doing computerized tomographic scan or magnetic resonance imaging. When do we send the patients for radiologic examination? Again, the patient has to be in a stabilized condition. Patients who have already received magnesium sulfate and patients whose blood pressure already has been controlled should be accompanied to the radiology department by faculty or a senior resident, who should be prepared to administer more magnesium sulfate or to perform emergency intubation.

Experience with the EndoPap device for the cytologic detection of uterine cancer and its precursors: A comparison of the EndoPap with fractional curettage or hysterectomy

James P. LaPolla, MD,[a] Santo Nicosia, MD,[b] Charles McCurdy, MD,[c] Curtis Songster, MD,[d] Eugene Ruffolo, MD,[b] William S. Roberts, MD,[a] Mitchel S. Hoffman, MD,[a] James V. Fiorica, MD,[a] and Denis Cavanagh, MD[a]

Tampa and St. Petersburg, Florida

Cytologic assessment of the endometrium with the EndoPap sampler was compared with curettage or hysterectomy in 249 women with symptoms. The sensitivities for the detection of primary corpus cancer and hyperplasia were 0.90 (59/66) and 0.58 (18/31), respectively. All six cases of atypical endometrial hyperplasia were detected by the EndoPap device. Malignant EndoPap cytologic findings were present in 4 of 10 patients with a primary adnexal malignancy and normal endometrial histologic findings. Ninety-two percent of primary uterine cervical cancers were detected by EndoPap cytologic sampling. The specificity for the cytologic diagnosis of benign conditions was 0.93. EndoPap cytologic sampling has a reasonably high sensitivity for the detection of uterine cancers and preinvasive endometrial lesions with a high risk of progression to carcinoma. Further evaluation as to its usefulness in a screening program for uterine and adnexal cancers in postmenopausal women should be considered. (Am J Obstet Gynecol 1990;163: 1055-60.)

Key words: Endometrial cytology, uterine cancer

Endometrial cytologic sampling has lagged behind cervical cytologic sampling in its application and, most important, its impact on clinical practice. It is well known that the decline in the incidence of invasive cervical carcinoma has been primarily attributed to the widespread application of a cervical cytology screening program. A similar phenomenon has not occurred for endometrial carcinoma. Reasons for this are primarily because of the lack of an effective, inexpensive, and easy-to-use sampling method. In addition, greater expertise is needed to accurately interpret endometrial cytologic specimens, which frequently are unavailable on a routine clinical basis.[1] The EndoPap endometrial

cytologic sampler (Fig. 1) was developed as an inexpensive and simple device aimed at improving the detection of endometrial cancer through routine screening. Palermo et al.[1, 2] have previously published their experience with the EndoPap sampler and found that it was easy to use with little to no patient discomfort reported. Few reports exist that correlate endometrial cytologic specimens with histologic specimens obtained at curettage or hysterectomy.[3] We report our experience with the EndoPap device and compare cytologic accuracy versus histopathology in women with symptoms undergoing uterine curettage or hysterectomy.

Material and methods

The study was approved by the research and ethics committee on human experimentation of all three institutions participating.

The EndoPap sampler was used to sample the endometrium of 249 women, ages 40 years or more (67% >50 years), before endometrial curettage or hysterectomy while under general anesthesia. The indications for curettage or hysterectomy are noted in Table I. Twenty specimens were obtained at Tampa General Hospital, 126 at the H. Lee Moffitt Cancer Center and Research Institute, and 103 at Bayfront Medical Center. Women with previous endometrial biopsies within the preceding 1 week or prior radiation therapy were excluded from the study. EndoPap samples were taken primarily by resident housestaff under the supervision of the authors (J.P.L., C.M., J.V.F., M.S.H., W.S.R., D.C.). For most patients, the EndoPap device was inserted directly through the endocervical canal without prior dilatation into the endometrial cavity. The device contains six hooklets (three anteriorly and three posteriorly) near the tip that collect uterine cells and tissue microfragments as it scraped over the endometrial/endocervical surface. Four to five strokes of the device were applied to both the anterior and posterior uterine surfaces. After the sampler was withdrawn, the specimen was smeared on glass slides in a manner similar to that used for cervical Papanicolaou smears and then immediately fixed by immersion in 95% ethyl alcohol. The cytologic smears were screened at each institution by cytotechnologists, and the final interpretation was made by one of the authors (S.N.-H.L.M., C.S.-B.M.C., and E.R.-T.G.H.). Clinical information and histologic diagnosis were restricted from the cytopathologist. The tissue report was considered the definitive diagnosis. Of the 249 patients evaluated, 38 had uterine curettage and 211 had hysterectomy after cytologic sampling. Eight patients had smears that were unsatisfactory because of insufficient cellularity or improper fixation, leaving 241 (96%) with adequate cytologic specimens.

Cytologic criteria. Tissue fragments obtained by EndoPap sampling included the following: (1) surface epithelial sheets, (2) gland segments, (3) stromal aggregates, and (4) variable endocervical tissue. Surface epithelial sheets appeared as flat or folded monolayers with sharp edges, occasional glandular opening or ostia, and evenly spaced nuclei containing micronucleoli. Gland segments appeared as tubular fragments of various lengths with irregular or rounded ends and were composed of monolayered epithelium with evenly spaced nuclei and micronucleoli. Stromal aggregates were identified as loosely cohesive groups with indistinct cell borders and round, oval, or bean-shaped nuclei usually containing a single micronucleolus. Endocervical tissue fragments represented a frequent contaminant of EndoPap samples and were distinguished from endometrial tissues on the basis of smaller size and the presence of larger, palisading cells, with larger nuclei frequently displaying characteristic protrusions of nipples.[4]

EndoPap samples were stained by the Papanicolaou method. In the early phase of this study, a cytologic classification of atypical endometrial cells was given to a few samples if cellular findings revealed nuclear enlargement with increased nuclear cytoplasmic ratio, nuclear hyperchromasia, and focal or irregular distribution of chromatin particles as reported as Cherkis et al.[5] Later, samples were divided into the following diagnostic groups: (1) normal, (2) consistent with endometrial hyperplasia, (3) consistent with endometrial hyperplasia with atypia, (4) consistent with endometrial adenocarcinoma or other specified uterine or extrauterine malignancies (i.e., endocervical adenocarcinoma or cervical squamous cell carcinoma). Criteria for assigning endometrial samples to each diagnostic group

were those of Palermo,[1] Meisels and Jolicoeur,[6] Ayer et al.,[7] and Massoni and Hajdu.[8]

The statistics presented are also generated from the group of 241 patients with adequate cytologic specimens. "Sensitivity," the ability to detect disease, was calculated by dividing the true positive by the total number of patients with corpus malignancy or endometrial hyperplasia and multiplying by 100. "Specificity," the ability to determine the actual percentage of disease-free patients, was calculated by dividing the number of true negatives by the total number of patients who did not have carcinoma or endometrial hyperplasia and multiplying by 100.[9]

Results

In 249 women undergoing EndoPap sampling, 13 (5%) required cervical dilatation before sampling because of cervical stenosis. Of the 241 patients with satisfactory EndoPap cytologic specimens, 66 patients had a positive tissue diagnosis of corpus malignancy, and 59 (0.90) cases were detected by cytologic study. In seven the cytologic findings were normal. The reasons for false negativity included cancer within a small polyp (two), small focal carcinoma (<1 cm, two patients), and sampling error (three).

Thirty-one patients had endometrial hyperplasia established by tissue diagnosis, and 18 cases were detected by abnormal cytologic findings (sensitivity, 0.58). All six women with atypical endometrial hyperplasia had abnormal endometrial cytologic findings. Abnormal EndoPap cytologic studies were noted in 13 of 19 patients with adnexal malignancies who had no symptoms of uterine disease. Nine had concomitant endometrial disease (endometrial hyperplasia, seven, cancer, two). In the remaining 10 patients, 4 (3 Stage IC or greater; 1 Stage IA) had malignant EndoPap cytologic findings with benign endometrium on histopathologic examination. Twenty-three of 25 cancers of the uterine cervix were detected by EndoPap cytologic sampling.

Of 109 patients with histologically normal endometrial samples obtained by curettage or hysterectomy and no gynecologic malignancy or hyperplasia, the cytologic diagnosis of the endometrial state was abnormal in eight patients, consisting of atypical endometrial cells or hyperplasia. Although atypical reactive endocervical cells were noted in 13 patients with a benign diagnosis, this finding was not considered a false-positive diagnosis of the endometrial state. The specificity of cytologic diagnosis for the benign endometrial state was 0.93 (101/109) (Table II).

Comment

Before the establishment of a screening program for uterine malignancies, the screening device must be carefully evaluated. In addition to providing an adequate specimen, the screening device must be easy to use (requiring little to no other instrumentation) and have a high likelihood of achieving successful insertion within the uterine cavity. In the present series the EndoPap sampler had a 95% successful rate of insertion without the need for cervical dilatation. In a previous study by Meisels et al.[10] in which the EndoPap sampler was used in an outpatient setting, uterine insertion was unsuccessful in 10% because of cervical stenosis. The device's small diameter of 2.0 mm facilitates successful insertion into the uterine cavity, particularly in comparison with other samplers with larger external diameters. This is especially important for postmenopausal patients, who have a higher incidence of cancer of the upper genital tract and in whom atrophic cervical stenosis is not uncommon.

Four percent (8/249) of the EndoPap samples were considered inadequate for cytologic diagnosis because of air drying artifacts or insufficient cellular specimens. On the basis of their experience with various endometrial samplers, Iversen and Segadal[11] reported that adequate endometrial samples were obtained more often on cytologic examination than after curettage in the postmenopausal patient with atrophic endometrium. The low rates of inadequate or unsatisfactory smears observed in our study and by others serve to enhance the cost-effectiveness of the use of endometrial cytologic sampling when applied to a screening program for uterine cancer, especially in postmenopausal women.[2, 9, 12-17]

EndoPap cytologic findings were abnormal in 90% of our patients with corpus cancer. In 10 patients the cytologic diagnosis, although less than malignant, would have directed the clinician to perform curettage to rule out the presence of malignancy. The EndoPap sampler method achieves a sensitivity for the detection of corpus cancer comparable with other incompletely controlled studies that use endometrial cytology instruments with differing methods of cell collection (Table III). EndoPap cytologic findings were falsely negative in 10% of corpus malignancies. Although focality

of lesion was the main reason, a few more diffuse lesions were not detected. However, even uterine curettage has been reported to overlook endometrial lesions in as many as 10% of patients in whom curettage preceded hysterectomy.[18]

Endometrial hyperplasia was more difficult to distinguish from normal endometrium than was carcinoma by EndoPap cytologic sampling. The sensitivity of cytologic sampling for the detection of endometrial hyperplasia has long been recognized to be low. In a previous report, Palermo et al.[2] noted that the sensitivity for cytologic detection of endometrial hyperplasia was only 32%. Meisels and Jolicoeur[6] have published morphologic criteria for the cytologic assessment of hyperplasia and reported a sensitivity of 52%. Using similar criteria our overall sensitivity for the detection of hyperplasia was comparable. Our false-negative results were often associated with lower-grade hyperplasias. To improve the cytologic accuracy for the detection of low-grade hyperplasias, further research into improving morphologic cytologic criteria will be necessary.

Malignant EndoPap cytologic specimens were obtained in 4 of 10 patients with adnexal malignancies but normal endometrial pathologic findings. In evaluating the adnexal mass in postmenopausal women, Finkler et al.[19] have shown that the addition of sonography and serum tumor markers has provided better discrimination for predicting the presence of a malignant ovarian neoplasm than does physical examination alone. Our findings suggest that the addition of endometrial cytologic sampling may provide further discriminatory value in differentiating benign from malignant adnexal masses.

Currently within the United States based on American Cancer Society statistics, cancer of the uterine corpus is the most common malignancy of the female genital tract, followed by ovarian and cervical cancers.[20] Although corpus and ovarian cancer occur primarily

in postmenopausal women, cervical carcinoma is certainly not uncommon in the postmenopausal age group. According to Piver,[21] about 25% of all cervical carcinomas are in postmenopausal women, with 40% of the expected 7000 annual deaths occurring in this age group. Based on current American Cancer Society guidelines, the frequency of screening cervical cytologic samples is left to the discretion of the physician after a woman has had three adequate normal cervical Papanicolaou smears.[20] After three normal smears, there are currently no established or widely accepted guidelines to screen for cancer of the female genital tract. Debate currently exists regarding the value and effectiveness of endometrial sampling for screening women without symptoms for corpus neoplasms, and no technique of proven value is available to screen for the early detection of ovarian cancer.[22, 23] Despite the lack of universally acceptable guidelines, many clinicians continue to perform annual pelvic examinations and cervical Papanicolaou smears in postmenopausal women, recognizing the higher risk of malignancies of the upper genital tract in this age group. On the basis of our experience and previous reports, we suggest that the EndoPap sampler undergo further evaluation regarding its usefulness in a screening program for the detection of uterine and adnexal cancers in postmenopausal women.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

DR. BENEDICT B. BENIGNO, Atlanta, Georgia (Official Guest). The incidence of endometrial carcinoma in the United States is more than twice that of cervical carcinoma (36,000 vs 14,000), a reversal of the ratio seen a generation ago. The incidence rate of 21.1/100,000 with a lifetime risk of 2.4%, making this the most common gynecologic malignancy. Only the risks of carcinoma of the breast (9.0%) and colorectal cancer (5.7%) are greater.[1]

The vast majority of these neoplasms are diagnosed after tissue sampling of the endometrium because of postmenopausal bleeding. The only cytologic screening procedure at the time of the annual pelvic examination for thse patients remains the traditional Papanicolaou smear, even though it has been known for many years that such cytologic sampling will miss about 50% of endometrial cancers. The incidence of poor prognostic parameters such as high-grade histology, deep myometrial invasion, and nodal metastasis is significant, and one cannot help but wonder about the extent to which routine endometrial screening might one day diminish such parameters.

The ideal screening procedure should be safe, painless, easy to perform, and highly reliable. It is unfortunate that the patients presented in this series had the endometrium sampled under general anesthesia. Not

only can no comment be made regarding the pain associated with this procedure, but it is possible that a more representative tissue sample was obtained because the patient was not awake. Despite the fact that the samples were obtained under anesthesia, the EndoPap device had only a 90% sensitivity for the detection of corpus cancer, which was the second lowest in the series presented in Table III.

This device had the same high failure rate with respect to endometrial hyperplasia (13/31) as is reported in most other series, but it is encouraging to note that all six cases of atypical endometrial hyperplasia were detected. The incidence of cancer was more than twice that of endometrial hyperplasia, but this is most likely because this study investigated the endometrial cytology of patients with serious pelvic disease and was not designed as a screening study.

It was very gratifying to see that 13 of 19 patients with an adnexal cancer had positive endometrial cytologic findings, and of these 19 patients, only two had a concomitant malignancy in the endometrium. Routine cytologic screening of the uterine cervix is virtually useless with respect to cancer of the ovary, and I doubt whether the use of serum CA 25 or pelvic ultrasound examination will have much of an impact as screening procedures for ovarian cancer.

It would appear that the detection of cancer of the ovary is not the only "bonus" in this study. In 23 of the 25 patients with carcinoma of the cervix, the EndoPap device detected the lesion. Although most cancers of the endocervix are easy to detect with the Papanicolaou smear and the colposcope, it is not uncommon for cancers beginning high in the endocervical canal to have a negative Papanicolaou smear and elude even the most experienced of colposcopists.

In Norway, Iversen and Segadel[2] used endometrial cytologic sampling as the first diagnostic procedure in the evaluation of patients with postmenopausal bleeding, which reduced the hospital curettage rate by 70%, a figure that they claim will eventually be as low as 90%. In the United States approximately 210,000 hospital curettages are performed each year for postmenopausal bleeding or for the screening of postmenopausal women. At an average cost of $1925, a 70% reduction would represent an annual savings of 283 million dollars.[3]

In this very fine and timely study, the authors call attention to the inadequacy of the annual pelvic examination and cervical Papanicolaou smear in the detection of malignancies of the upper genital tract. Rather than expand on this work in the form of a screening study as the authors have suggested, have we reached the point in which cytologic assessment of the endometrium should be part of the routine annual evaluation of postmenopausal patients?

DR. LAPOLLA (Closing). I think we might be able to do a little bit better in our approach to postmenopausal patients than we are currently doing with the cervical Papanicolaou smear. An evaluation of our experience points out that the addition of office endometrial cytologic sampling may be of value in our screening approach to postmenopausal women. There are many issues with respect to screening patients for endometrial cancer that are not addressed in this study, and there are pros and cons for screening for endometrial cancer, which you will note in the literature. My point behind the use of office endometrial cytologic sampling is that it can be used for more than just screening for endometrial cancer. I tried to point out in the article that the incidence of invasive cancers of the upper genital tract, the cervix, uterus, and ovary, are fairly significant in the United States. You have to examine all three types of cancers in postmenopausal women and not just focus on endometrial cancer. Many noted authorities on this subject have proposed that endometrial cytologic sampling or screening not be used primarily, because the overall death risk for patients with endometrial cancer is really fairly low. I believe that it is better to look at the total picture of genital tract cancer in postmenopausal women. About 25% of all cervical cancers in the United States occur in postmenopausal women, and most women with ovarian cancer and endometrial cancer are postmenopause; thus I think you have to examine all three major types of malignancies of the upper genital tract in terms of screening. We cannot just focus on the issue of endometrial cancer.

Diagnosis and management of prenatally detected myelomeningocele: A preliminary report

William A. Hogge, MD,[a, b] Jeffrey S. Dungan, MD,[a] Mark P. Brooks, MD,[a] Susan A. Dilks, MD,[b] Patricia L. Abbitt, MD,[a, c] Siva Thiagarajah, MBBS,[a, c] and James E. Ferguson, MD[a, c]

Charlottesville, Virginia

Our experience with 23 cases of fetal myelomeningocele provides preliminary information on the outcome of these infants diagnosed in utero and managed by a multidisciplinary team. The mean age of diagnosis was 23.7 weeks (range, 16 to 34 weeks). Mean gestational age at delivery was 36.9 weeks in the 14 patients who elected to continue their pregnancies. None of the 11 infants with lumbosacral or sacral lesions developed significant ventriculomegaly before term. Of the three patients diagnosed with thoracolumbar lesions, two had progression of ventriculomegaly necessitating early delivery at 32 to 34 weeks of gestation. These preliminary findings suggest that a coordinated prenatal and neonatal approach appears to result in a favorable prognosis for infants with myelomeningocele, but that neonatal complications are common, requiring careful monitoring and aggressive management. (AM J OBSTET GYNECOL 1990;163:1061-5.)

Key words: Myelomeningocele, prenatal diagnosis, spina bifida

The advent of high-resolution ultrasonography and the widespread implementation of maternal serum α-fetoprotein screening have led to a marked increase in the number of cases of spina bifida detected in utero. However, little information is available regarding the natural history and progression of prenatally detected myelomeningocele. We report the preliminary experience of an ongoing longitudinal evaluation of infants diagnosed in utero with myelomeningocele, who were managed both prenatally and postnatally by a multidisciplinary team.

Material and methods

From July 1, 1986, to Oct. 31, 1989, 23 patients were referred to the Prenatal Diagnosis and Treatment Center of the University of Virginia Health Sciences Center for the management of pregnancies complicated by fetal myelomeningocele. Each patient had an initial ultrasound examination to determine the size and level of the lesion, possible existence and degree of ventriculomegaly, and the presence of other fetal abnormalities. A fetal karyotype was obtained by either amniocentesis or percutaneous umbilical blood sampling in all patients.

On completion of the diagnostic evaluation, the family met separately with a geneticist and a developmental pediatrician for counseling regarding the findings in the fetus and their implications for neonatal management. Discussions also centered on the long-term prognosis of spina bifida in children with similar lesions. Options for pregnancy management, including pregnancy termination, if applicable, were discussed in a nondirective counseling fashion.

Patients who chose to continue their pregnancies were followed by serial ultrasound evaluations every 3 to 4 weeks. Delivery was performed by cesarean section when fetal lung maturity was attained or earlier if significant ventriculomegaly (cortical mantle thickness <10 mm) was documented. Each newborn infant had an initial examination to determine the level of the lesion, the level of neurologic deficit, and the presence of other malformations. Follow-up examinations and developmental testing was performed by a multidisciplinary team of developmental specialists at the Kluge Children's Rehabilitation Center of the University of Virginia, under the direction of one of the authors (S.A.D.).

In pregnancies in which termination was chosen, autopsies were performed in all cases to confirm the ultrasound findings. Postmortem radiographs were obtained in all cases.

*Two patients electively delivered at 32 and 34 weeks, respectively, because of significant ventriculomegaly.

Results

The characteristics of continued pregnancies are compared with those of terminated pregnancies in Table I. For the total group the mean gestational age at diagnosis was 23.7 weeks, with a range of 16 to 34 weeks. The distribution of the level of the lesion and the incidence of associated abnormalities were similar in both groups. Neither of the renal malformations was detected on the initial sonogram. Of the 14 continued pregnancies, 13 had ventriculomegaly at the time of diagnosis; 9 of 12 terminated pregnancies had ventriculomegaly. No fetus in either group had significant enlargement of the ventricles at the time of initial diagnosis. However, the time of initial diagnosis was significantly earlier (7 weeks) in those patients choosing termination.

Table II provides an outline of the natural history of in utero–detected myelomeningocele. Of the 14 patients only 2 had progression to significant ventriculomegaly. Both fetuses had thoracolumbar lesions and were delivered at 32 and 34 weeks, respectively, because of the degree of ventricular enlargement. Of the remaining 12 patients, all were electively delivered when fetal lung maturity was documented except one, who delivered at 35 weeks after unsuccessful treatment for preterm labor. All fetuses with lesions above the sacral area required postnatal shunting for progressive ventriculomegaly despite the absence of progression in utero in 80% of the cases.

In Table III outcome criteria for surviving infants with at least 12 months of follow-up are depicted based on level of lesion. The cases are equally distributed in each category, and no striking differences are seen between groups. There are no cases of significant developmental delay in any category. Two of 10 infants required posterior fossa decompression because of episodes of apnea.

Apnea also contributed to the deaths of 2 of 14 study patients for a mortality rate of 14.3%. One death occurred in a 15-month-old child because of bowel necrosis after a prolonged apneic episode. A second child died at home at 1 month of age, presumably the result of an unrecognized apneic event.

Comment

In recent years a marked increase in the number of cases of prenatally detected myelomeningocele has been documented.[1, 2] Providing families with accurate information regarding the natural history and prognosis, however, has been limited to extrapolations made from data in which myelomeningocele was detected in newborn infants. Much of this published information also predates the significant advances made in neonatal intensive care.[3, 4] Obtaining longitudinal data at the time of in utero diagnosis and continuing through the first few years of life is essential for the counseling of families in whom a fetus with myelomeningocele is detected. In this report we present our preliminary information from a project undertaken to study the effects of a coordinated management approach, both

prenatally and neonatally, on the outcome for children with myelomeningocele.

Although the number of cases to date is small, some interesting observations have been made. First, fetuses with lumbosacral or sacral lesions do not have a significant risk of progression of ventriculomegaly in utero. The finding was surprising in view of the fact that 10 of the 11 fetuses had enlarged ventricles at the time of diagnosis, and nine required postnatal shunting. In contrast, two of the three patients with thoracic lesions had progressive ventriculomegaly, which necessitated early delivery. However, the good outcome in both cases suggests that an aggressive management approach may be associated with a good prognosis for mental development. We recognize that bias may be introduced by the significantly later time of initial diagnosis in the group of pregnancies that were continued; however, the distribution of levels of lesion and the degree of ventriculomegaly were similar in both groups. Therefore the outcome in the continued pregnancies should accurately reflect that for the total group.

In 10 patients a mean postnatal observational time of 23 months has been completed, and the preliminary findings suggest that this coordinated prenatal and neonatal management results in a favorable prognosis. None of the infants have significant developmental delay. The mild delays seen in four patients are likely to be a reflection of the heavy weighting of the testing modalities on tasks that require normal lower motor function, skills not possible in these infants. Our data also support the assertions of Shurtleff et al.[4] and McLaughlin et al.[5] that infants diagnosed in utero and born without trauma have few contraindications to immediate surgical care, a factor that was shown in their studies to be associated improved outcome. Likewise, McLone[6] has documented similar survival rates and mental development in infants with the use of prompt surgical management.

However, neonatal complications are quite common and resulted in significant morbidity (2/10) and mortality (2/14) in the children followed for >12 months. Each of these occurrences appears to be directly related to apneic episodes. In the two surviving children, posterior fossa decompression resulted in resolution of the problem. These findings suggest that careful monitoring of these infants and aggressive management are an essential part of the long-term care of children with myelomeningocele.

The optimal mode of delivery for the infant with myelomeningocele is controversial. Chevernak et al.[2] suspected that cesarean section might be a potentially beneficial procedure based on their review of older literature that appeared to indicate a detrimental effect on neurologic outcome in infants delivered vaginally. More recently Benson et al.[7] reviewed retrospectively the records of 75 infants with open spina bifida. They found no significant difference in mortality, incidence of neonatal meningitis, or developmental status at 1 year of age between infants delivered vaginally and those delivered by cesarean section. However, interpretation of their data is difficult because of small numbers and because 40% of patients who had cesarean section had prior labor. In addition, the incidence of neonatal meningitis was quite high (4/72 infants), and three of these infants were in the vaginally delivered group. Infection of the central nervous system is known to be a limiting factor in the intelligence of children with myelomeningocele.[8] Elective cesarean section before labor provides an aseptic, atraumatic mode of delivery. Infants born in this manner have fewer contraindications to immediate surgical care, and there is the potential for a better outcome.[5] However, only carefully controlled, prospective clinical studies will provide the necessary data to resolve this management dilemma.

Our preliminary data indicate that the finding of a myelomeningocele in the fetus can be associated with a good prognosis. A coordinated management approach beginning at the time of diagnosis appears to enhance the potential for a favorable outcome. Further study is needed before more precise prognostic statements can be made.

Discussion

Dr. Richard C. Taft, Greenville, North Carolina (official guest). Dr. Hogge and colleagues are to be commended for their endeavors to document the natural history of in utero–diagnosed meningomyelocele. They have confirmed that ventriculomegaly usually coexists with meningomyelocele at the time of diagnosis by sonography and that higher lesions are more likely to have progressive ventriculomegaly. Also atraumatic delivery at term by cesarean section is recommended. Interestingly, they report that 9 of 10 neonates required shunts despite no progression in utero. Perhaps this is a result of the now-aggressive neurosurgical approach at the time of delivery. McLaughlin et al.[1] report an increased frequency of surgical treatment in neonates once thought to have a poor prognosis. This approach allows the degree of injury to be halted at birth and therefore a more favorable long-term outcome.

Hogge et al. recommend intervention in infants with progressive ventriculomegaly, but the number of infants is small and he had no control group. Indeed, pediatricians debate the validity of using cortical mantle thickness as an accurate predictor of long-term development. I also find it interesting that infants with higher clinically, more significant lesions in the thoracic area, which supposedly have a graver long-term prognosis, were not in the group that developed the severe complication of brain-stem herniation.

As Dr. Hogge and colleagues continue this longitudinal study of neural tube defects, I would find it interesting if they could define a graphic correlation between the lateral ventricle/hemispheric width ratio and the severity of morbidity and mortality. Screening criteria also need to be established for neonates at risk for herniation because 25% of the infants in this study and that by Chevernak et al.[2] developed brain-stem compression. Perhaps in utero evaluation of fetal breathing movements or fetal bradycardia might identify this group of infants. Also, sonographic evaluation of the posterior fossa contents, such as cerebellar transverse diameter, might be helpful as an indicator.

I would also like Dr. Hogge to comment on the sonographic sign of angulation or pointing of the fetal frontal bone as an indicator of an associated neural tube defect as reported by Penso et al.[3] If confirmed, this sign will help all obstetricians who do anatomic surveys with sonography to diagnose meningomyeloceles more frequently.

In summary, the study of Hogge et al. demonstrates the importance of the multidisciplinary approach to a very severe developmental defect that in the past has always led to death or disability. Early prenatal diagnosis armed with the knowledge of the natural history of neural tube defects will allow parents to make informed decisions about continuing their pregnancy with hope or terminating when the prognosis is poor.

3. Penso C, Redline RW, Benacerraf, BR. A sonographic sign which predicts which fetuses with hydrocephalus have an associated neural tube defect. J Ultrasound Med 1987; 6:307-11.

Dr. Alfred H. Moffett Jr., Leesburg, Florida. As a clinician, I feel that this is a very important paper. I personally managed a case that emphasizes several points. First, it was followed by both the clinician and the academician. Second, the ultrasound diagnosis of fetal meningomyelocele led to delivery by cesarean section at 38 weeks' gestation. The infant was taken immediately to surgery by the pediatric neurosurgeon. That child now runs up and down the hallway in my office. I consider this the therapeutic triumph of my career. I really feel as though this is an entity that if found early, does give hope for successful treatment. How are the children doing with their subsequent development?

Dr. William Kirkley, Fort Lauderdale, Florida. I would like to ask Dr. Hogge if he reviewed Dr. Lorber's work in England on these children. About 12 years ago, he wrote a paper on this, in which he took a very aggressive surgical approach once the child had delivered. His conclusion after following these children for many years was that not one of them ever married successfully, and I do not think any of them were ever gainfully employed. His conclusions were "What have thou wrought?"

Dr. Hogge (Closing). I thank Dr. Taft for his excellent comments and confirm that we in fact found

the ultrasound findings to be very much as has been described. Most, if not all, of the infants who were diagnosed before 26 weeks had the frontal bone sign known as the lemon sign. Unfortunately, they also had the very small posterior fossa that can be seen by looking at the cerebellum. It was not helpful in terms of what infants would have difficulties in the neonatal period. There were also no findings on neonatal ultrasound examinations that were helpful in discriminating between those who would have apneic episodes and those who would not.

I will go to the last question first because I think it relates to all the questions that were asked; that is, what is the ultimate prognosis for these children? The ultimate prognosis for these children is very different in 1990 than it was at the time of Dr. Lorber's work. These children are now, as you are well aware, mainstreamed into school systems. They are also taken care of by multidisciplinary teams that help with the management in the areas of physical therapy, occupational therapy, and so forth, and there is no reason that these children cannot be gainfully employed. As is well known in the recent literature, the incidence of mental retardation is these children is quite low. It is higher than that in the general population but is significantly lower than seen at the time of Dr. Lorber's original work. There is no reason, other than being wheelchair bound in the cases of lesions above L-2, that these children should not grow up and be gainfully employed and be members of this organization for that matter.

These children are not running around in my office because they do in fact have significant neurologic lesions. In those children in whom the lesion is above L-2, they will be wheelchair bound. As you move down the spine from that point, we talk about braces. In some cases we expect those with the lower lumbar and sacral lesions to walk with the aid of braces, but in fact they should have a good outcome. We will present to you in another 6 years the data on these children when they are in school. We should then have a better idea of their ultimate prognosis at that point.

Outpatient obstetric management of women with type I diabetes

F. John Bourgeois, MD, and Jeanne Duffer, MSN
Charlottesville, Virginia

Conventional obstetric management of diabetic women has frequently incurred extensive hospitalization. Although this approach improved perinatal results for these women and their infants, it is costly and cumbersome. The 3-year experience of an outpatient diabetic obstetric clinic is compared with the results obtained at the same facility during 5 previous years when hospitalization was used more extensively. Perinatal mortality and morbidity were not different in 51 type I diabetic women managed almost entirely as outpatients when compared with 58 similarly complicated diabetic patients receiving more conventional management. Mean prenatal admissions (1 vs 2, $p = <0.01$), mean prenatal hospital days (6 vs 12, $p = 0.05$), and prolonged delivery admissions of >7 days (31% vs 69%, $p = < 0.01$) were significantly less. Outpatient obstetric management of diabetic women efficiently decreases maternal morbidity without increasing infant morbidity and mortality. (Am J Obstet Gynecol 1990;163:1065-73.)

Key words: Outpatient care, type I diabetes, pregnancy

In diabetic pregnancies, management directed at improving fetal outcome has seldom been balanced by a corresponding effort to improve maternal morbidity. Maternal hospitalization, often extensive, is still considered a fundamental measure in the management of pregnant diabetic women.[1-3] Maternal hospitalization contributes to maternal morbidity. It does not improve perinatal morbidity or mortality.[4-6] Reported rates of cesarean section are high.[2-4, 7, 8]

Successful pregnancy in diabetic women is currently measured more often in infant morbidity and the incidence of congenital anomalies than in perinatal mortality. At least in settings offering intensive preg-

nancy care, perinatal mortality rates have greatly improved.[1-3, 7, 9] Congenital anomalies remain a significant cause of fetal morbidity and mortality despite efforts directed at prevention.[10, 11] The incidence of infant morbidity unrelated to anomalies has decreased.[2, 3, 8, 12]

This study was undertaken in pregnant women with type I diabetes mellitus to determine the efficacy of outpatient management in reducing maternal morbidity without increasing perinatal morbidity and mortality.

Material and methods

In 1985 the University of Virginia Obstetrical Service organized an outpatient clinic for type I insulin-dependent diabetic women in an attempt to minimize hospitalization by providing comprehensive ambulatory care. Since then, 51 pregnancies have been managed in 47 women with type I diabetes mellitus (group A). The results of this project are compared with those of the preceding 5 years, when 58 pregnancies complicated by diabetes were managed by use of routine antepartum hospitalization (group B). Pregnancies in both groups complicated by spontaneous and elected abortion were not included in this analysis.

Throughout pregnancy, women were treated by an obstetric nurse trained in diabetic management, an attending obstetrician/internist, a resident assigned on a rotating basis, and a dietician. Initial visits for most women did not occur until late in the first trimester or early second trimester. Some women were not seen until the third trimester. Only one woman had counseling before a first pregnancy. Most women were rural and indigent, many lived at least 1 hour from the clinic, and only nine had medical insurance.

All were treated with combinations of intermediate- and short-acting or long- and short-acting insulin. Human insulin was used exclusively since 1986.

During the first year of the study, women were hospitalized for instruction if initiating insulin therapy, inexperienced with home glucose monitoring, or very poorly controlled. This practice was discontinued thereafter. All patients except one used home glucose monitoring. Glucose monitor readings were correlated with hospital laboratory glucose determinations. Patient contact by visit or telephone occurred as often as daily. Fasting, premeal, and bedtime glucose measurements were considered good at levels below 100 mg/dl at fasting and 120 mg/dl at other times. Hemoglobin A_1 determinations were made at the outset of care and subsequently every 2 months. These were done with an affinity chromatography method having an upper limit of normal of 7%. Clinical assessment of glucose control was made primarily on the basis of glucose measurements. Hemoglobin A_1 levels were used to verify glucose levels and in the analysis of data for this report.

All women had retinal evaluation by an ophthalmologist skilled in the assessment of retinal disease. Women with proliferative retinopathy or advanced benign retinopathy were assessed each month. Renal function was evaluated each trimester with 24-hour urine collection for creatinine clearance and total urinary protein. Urinalysis was done regularly to screen for infection. An electrocardiogram was done on all women with vascular disease.

An ultrasound examination was performed when possible at 16 to 20 weeks' gestation to screen for fetal anomalies and to confirm gestational age. Scans were repeated in the second trimester to evaluate growth. All had α-fetoprotein testing, and karyotyping was done on samples obtained by amniocentesis or chorionic villus sampling when justified by risk. Women seen initially at more advanced gestational age had ultrasound examinations as soon as they were seen and did not have α-fetoprotein testing.

Antepartum fetal testing was begun at 30 weeks' gestation in women with vascular disease, poor control, or special risk. They were tested weekly until 35 weeks' gestation and thereafter three to seven times a week until delivery. In others it was started at 32 weeks' gestation. In stable women without vascular disease, tests were done weekly until 37 weeks' gestation and three times each week thereafter. The nonstress test was primarily used, with contraction stress tests, biophysical profile and Doppler ultrasound studies reserved for situations in which the results of the nonstress were not reassuring.

Endometritis	2	4	—	8	14	—	$p = <0.05$

When the induction of labor was planned, amniotic fluid was assayed for the lecithin/sphingomyelin ratio and phosphatidylglycerol to determine fetal pulmonary maturity. The fetus was considered mature when the ratio was 2 and phosphatidylglycerol was present. Women were allowed to go into spontaneous labor unless there were contraindications but had induction of labor at 40 weeks if undelivered otherwise by then. Some had earlier induction if the cervix were very favorable. They had amniocentesis for maturity studies. These women were admitted on the day of induction of labor, and blood glucose level was maintained at approximately 100 mg/dl with a continuous infusion of glucose and insulin.

All deliveries were attended by pediatricians, and infants were admitted according to need either to the normal newborn nursery or the intensive care unit. Infants were considered hypoglycemic when glucose levels were <45 mg/dl. Hyperbilirubinemia was diagnosed when bilirubin levels were >12 mg/dl.

Statistical analysis was performed by means of the Student *t* test, χ^2 analysis of variance, and Fisher's exact test.

Results

The 51 women in the outpatient study group (group A) did not differ from the 58 women treated more conventionally (group B) in age, parity, or White classification of diabetes (Table I). There were 41 women in the study group and 53 in the comparison group who were classified as B through D. The numbers in each class within groups were similar. Ten women in group A and five in group B had diabetic nephropathy. None had heart disease.

As shown in Table II, at initial evaluation, glucose control, as reflected by hemoglobin A_1, was poor in most study group women. Seven women had normal hemoglobin A_1 at presentation, and blood glucose values indicated good control. Nine women had a level of <10%. The mean for the group was 12%. By delivery, 31 women (61%) had hemoglobin A_1 levels of <10% and the mean had decreased to 9.2%. Near-normal levels (<8.5%) were obtained in 21 women (41%). Insufficient data exist to characterize glucose control accurately in group B women. However, with the exception of glucose meter use and emphasis on outpatient treatment, management methods and goals were similar.

Maternal morbidity. Initially the study objective was frustrated by the perceived need to hospitalize for the initiation of insulin therapy and glucose monitoring and also to redirect poorly controlled women. In later cases hospitalization was reserved for illness. Group A women were hospitalized less often and for shorter durations than previously treated women. The mean number of prenatal admissions was significantly less for group A women (Table III), and hospitalizations were more often limited to 6 days or less. Compared with earlier patients, twice as many in the study had either no confinement or only one and used half as many hospital days (6 vs 12, $p = < 0.05$) (Table III). In addition to regular antenatal admissions, prolonged admission for late pregnancy monitoring and delivery was common among women treated before the project. Delivery admissions >7 days were far more common in group B women that in those included in group A (69% vs 29% $p = < 0.01$).

Rates of cesarean section were the same in the two groups (group A 50% vs group B 45%, p = NS) (Table III). Endometritis after cesarean section was far more common in the earlier group. Preeclampsia was diagnosed significantly fewer times in group A women. No women in the study group had pyelonephritis. One woman in the study group required hospitalization for hypoglycemia. There were no instances of antenatal ketoacidosis. Data relating to the incidence of pyelonephritis and hypoglycemia in group B women were not examined.

Group A women with diabetic nephropathy are presented in Table IV. Seven had essentially normal newborn infants, and all 10 infants ultimately did well. Half were delivered by cesarean section, as was the case with

the entire group. Four of the 10 pregnancies were complicated by hypertension, seven by renal excretory insufficiency, and all by significant proteinuria, massive in all but two. All women but one had significant worsening of proteinuria during pregnancy. One woman is currently on renal dialysis 2 years after the pregnancy, and three are expected to require it in the near future. All but one had hemoglobin A_1 levels <10 by delivery, and seven had normal levels. Two of the three group A women with preeclampsia were among this set. Unstable retinopathy complicated the course in three women with diabetic nephropathy. One required laser photocoagulation repeatedly during the second and third trimesters, and one needed vitrectomy. The third had florid background retinopathy that regressed after pregnancy and did not recur during a subsequent pregnancy.

Newborn morbidity. Infants of diabetic women in the study group were significantly less likely to be delivered before term than group B subjects (57% vs 74%, $p < 0.01$) but not to suffer morbidity (Table V). The requirements for intensive care, neonatal hypoglycemia, low Apgar score, and respiratory distress syndrome occurred with similar frequency in both the

Maximum serum creatinine	*Hypertension*	*$HgbA_1$**	*Comment*
1.2	Yes	10.3	Preeclampsia, healthy infant

0.8	No	9.2	Background retinopathy, normal newborn
0.7	No	9.6	Background retinopathy, premature labor, normal newborn
0.8	No	7.3	Background retinopathy, normal newborn
1.8	Yes	7.3	Normal newborn
1.0	No	7.2	Background retinopathy, normal newborn
3.0	No	5.4	Proliferative retinopathy, vitrectomy at 28 weeks, normal newborn
1.8	Yes	5.1	Proliferative retinopathy, fetal distress, healthy infant

study and control groups. The incidence of large (>4000 gm) or small (<2500 gm) infants did not differ. Only neonatal hyperbilirubinemia differed (11% vs 45%, group A vs group B, $p = < 0.01$). The nine infants suffering from respiratory distress syndrome (18% of the group) are detailed in Table VI. Five of these nine pregnancies were complicated by either premature labor or preeclampsia. The remaining four (8%) were at least potentially preventable. One mild case occurred despite amniotic fluid studies indicating maturity.

Neonatal morbidity is examined in relation to the degree of blood glucose control in Table VII. The incidence of both respiratory distress syndrome and early delivery, but not other newborn complications, is significantly less in women who achieved a delivery hemoglobin A_1 concentration of <8.5% (4% vs 27%, $p = < 0.05$; 38% vs 73%, $p = < 0.05$). The incidence of respiratory distress syndrome in infants was not related to the severity of diabetic complications in study group mothers. This complication occurred in two infants born of women with nephropathy and in seven infants of mothers in White classes B, C, and D (20% vs 17%, p = NS).

Fetal anomalies occurred with equal frequency in group A and B subjects (6% vs 10%, p = NS) (Table V). In the study group pregnancies complicated by fetal anomalies, two of the three occurred in women with extremely poor glucose control during embryogenesis (Table VIII).

Perinatal mortality. Two pregnancy failures occurred in both groups A and B (Table V). In group A both failures occurred in women who were poorly controlled (Table IX). One was caused by a fetal anomaly incompatible with life and intrauterine death. The other, which was preventable, occurred in a pregnancy complicated by failure of the mother to comply with medical advice. This woman refused both antepartum testing and hospitalization despite extensive counseling. Intrauterine death occurred at 35 weeks gestation. The perinatal mortality rate in study patients, including both, was 39/1000. Excluding the second patient, it was 20/1000. The rate in group B was 34/1000.

Comment

Outpatient management of type I diabetic gravidas improves maternal morbidity without compromising perinatal results. Hospitalization is a morbid complication of pregnancy. It contributes to emotional and financial hardship for the woman and her family and constitutes unnecessary expense. Only when necessary to produce medical benefits otherwise unattainable is it justifiable.

Although pregnancies in diabetic women have been managed successfully with minimal hospitalization,[4-6] extensive hospitalization is still practiced.[2,3] The intensive metabolic control efforts in our outpatient clinic were of the same degree as used in the hospital and were conducted under dietary and activity circumstances far more realistic than those found in the hos-

pital setting. When women were initially brought under control in the hospital, they commonly required reestablishment of control once discharged. Hospitalization of women decreased as the project progressed and was less than that used by others in attempting outpatient management of pregnant diabetic women.[4]

Group B women are not true controls, but rather a historic comparison group. Hospitalization periods for these women might have been influenced by their known greater incidence of preeclampsia (22% vs 6%). Nevertheless, it is true that hospitalization was used routinely during the years of their treatment, that this group was hospitalized far more, and that results with this method of treatment were not better than in those hospitalized less.

Hemoglobin A_1 level is a useful indicator of the establishment of glucose control over time. However, it is flawed because of the lag in this value in relation to decreases in blood glucose values. This 8-week lag is reflected in the number of study group women who failed to achieve acceptable levels by delivery. Many of these women had good control and significant decreases in hemoglobin A_1, but were admitted to the program too late to achieve normal levels by delivery. Except for this problem, hemoglobin A_1 levels offer a simple means to assess the control of study subjects.

The cesarean section rate in the study group was lower[7, 8, 12] or comparable with that in other studies.[2, 3] It was not different between the groups. The attempt made in group A women to allow spontaneous onset of labor or to defer induction until the cervix was favorable was directed at lowering the cesarean section rate, a goal not achieved. It may be true that improvement of metabolic control might allow continuation of pregnancies closer to the point of cervical ripening. Fetal well-being thus obtained could reduce the need for early induction of labor or cesarean section. No reduction in the cesarean section rate was observed in our well-controlled women, or in a very well-controlled group reported by Jovanovic and Jovanovic.[3] Most of the surgical deliveries in this group were indicated by fetal distress, maternal complications, large babies, and prior cesarean sections. The decrease in endometritis after delivery seen in group A women might reflect the more extensive use of prophylactic antibiotics during the years of this project.

The incidence of preeclampsia in group A women was not only much less than in the control group but was less than rates reported previously in diabetic women[2] and equal to our general population.[13] Although others have attempted to link this incidence to metabolic control[4] the relatively poor control in a number of group A women, at least by virtue of hemoglobin A_1 level, suggests no such association.

The women in group A with severe vasculopathy had no perinatal loses compared with two loses in each group. They were also under better metabolic control. The incidence of preeclampsia, a difficult diagnosis in women with significant proteinuria, was high in this group. The continuing morbid course of diabetic nephropathy in new mothers is well illustrated by the continuing severe renal insufficiency seen in four women. Given the opinion that diabetic vasculopathy is a risk factor for fetal anomaly,[14, 15] it is of interest that none of the three malformed infants were born to women in this group.

Newborn infants suffered no greater incidence of complications in the group treated as outpatients. They were delivered more frequently at term than their counterparts in the earlier group, although this conferred no apparent benefit in reduced morbidity, except in the reduction of neonatal hyperbilirubinemia. Respiratory distress syndrome occurred in 18% of group A infants, an incidence similar to that reported in diabetic women elsewhere.[2] This form of morbidity was far less in group A subjects who were well controlled (Table VII), and compared favorably with similarly well-controlled women.[2, 3] No such association was observed for neonatal hypoglycemia, which occurred for group A babies as a whole with a frequency comparable with that seen in well-controlled subjects.[2] Large and small infants complicated pregnancy results without respect to maternal glucose control, and newborn intensive care requirements were not dependent on control. These mixed results may relate to the degree of control accepted as good in this study. Furthermore, many women included in group A were not seen until relatively late in pregnancy, and the influence of both duration and degree of control might be reflected. As previously noted, the use of hemoglobin A_1 level as the index of control is simple and convenient, and third-trimester values correlate well with mean glucose determinations derived from individual glucose measurements over preceding weeks.[2] Therefore, it is an adequate assessment of duration and degree of control in the context of this report and effectively eliminates from the good control group women (Table VII) whose control was markedly improved only late in pregnancy.

Two perinatal deaths occurred in each group. Excluding one group A woman in whom the loss was not related to outpatient status but resulted from the refusal of care, the perinatal mortality rate was 20/1000, which is similar to that observed in both inpatient[2] and outpatient studies.[4]

The incidence of fetal anomalies was low in the 109 pregnancies. In group A women, two of three pregnancies resulting in malformed infants had poor control. In group B it was very good. Too few women in this study were controlled before pregnancy to have any realistic influence on anomaly rate.

The women and infants of group A might have ben-

efited from earlier and tighter control. They would not have benefited from more extensive hospitalization. The establishment of control is less efficiently done in the hospital, and even very frequent fetal monitoring can be managed in a clinic. Outpatient management of diabetic pregnant women suffers from no disadvantageous results not already a problem with women more frequently hospitalized. Fetal anomalies and morbidity, the principal consequences of diabetic pregnancy, are no more prevalent as a result of the setting in which the patient is managed.

Discussion

DR. C. WILLIS SHERRER, Atlanta, Georgia (official guest). Dr. Bourgeois' paper is timely insomuch as it confirms what many of us have questioned for a long time: is it logical to place an individual in an artificial environment and formulate a treatment plan based on results of tests that likely will be invalid shortly after leaving this environment? We have often questioned the rationale, but as with so many other aspects of medicine, we are reluctant to change what is known, familiar, and comfortable.

The decade of the 1980s saw the development and refinement of home glucose monitoring, as well as continuous insulin infusion apparati. These innovations, combined with reliable techniques for the monitoring of fetal maturity and well-being, have made it immeasurably easier to manage and carry to maturity in many instances the insulin-dependent diabetic patient.

Dr. Bourgeois' paper is supportive of the overall movement in medicine toward outpatient management of situations that previously mandated hospitalization. For example, many operations are performed in outpatient settings that were previously considered an absolutely necessary inpatient procedure.

The author made the following points in his paper:

Maternal

A. The mean number of admissions was less in the study group and shorter than in group B.
B. Hospital stay at delivery was longer for group B.
C. Preeclampsia was less in group A.
D. Endometritis was less in group A.
E. Delivery routes were the same in both groups.

Newborn and fetal effects

A. The study group infants delivered later in pregnancy than group B.
B. The overall outcome in morbidity compared favorably in both groups.
C. Respiratory distress syndrome was lower in well-controlled pregnancies; however, overall the two groups were equal.
D. Fetal anomalies were the same in both groups.

Dr. Bourgeois makes the point that group B patients were for historical comparison only. I do not believe they are a true control group but were convenient.

There are a number of points to be derived from this study. First, the management is cost-effective. This is a finite amount of money available in the health care pool. If this pool is tapped too often and too deeply, resources will not be available in other needy cases. (At Piedmont Hospital in Atlanta, a 3-day stay to evaluate, educate, and institute treatment is about $1000.). Second, although no improvement in outcome was demonstrated in the study group, no harm was done either. Also, the close monitoring ("as often as daily" by telephone) compares favorably with inpatient care.

Although this is not the first paper to support outpatient management of pregnant diabetic patients, Dr.

Bourgeois' emphasis is unique in *total* outpatient management concept.

If these patients Dr. Bourgeois has studied in a university clinic situation can be motivated and educated to participate in their own care, imagine how much easier it would appear for us to take a group of private patients, who likely are better educated and motivated, through to a successful pregnancy outcome. Therefore this is a timely and supportive report and one from which all obstetricians should benefit.

Dr. Lawrence Devoe, Augusta, Georgia. I enjoyed this paper very much, and I think it supports a very important role of conscientious care in a very cost-effective setting. I have a few questions that came up during the presentation that I would like Dr. Bourgeois to address. The first is the use of hemoglobin A_{1c} as a method of monitoring glycemia. Most of us would agree that this method is of such long-term duration that it helps very little in understanding what our patients currently do at the time we see them. Second, how does chronic renal disease, such as that found in the nephropathy group, really affect the value of hemoglobin A_{1c}? Is the hemoglobin synthesis process affected by the nature of intrinsic renal disease?

The second question I have relates to the large number of patients in group A who had macrosomia. How often was this recognized before these patients were delivered and were these patients reviewed individually to confirm that their glycemic control met the standards of care that were established for this group?

Dr. Hugh Randall, Atlanta, Georgia. In this paper there was a push for outpatient management both in the private and public setting. I believe that if we try to look at cost containment, we will find that insurance companies will push just as hard and as far as they can without us trying to look for additional ways to do so. I am sure that there are many things that they pushed us into that are not particularly pleasing.

I believe that there are differences here, particularly in the incidence of marcosomia, toxemia, and endometritis and even subtle neonatal differences that may have been statistically significant and certainly would have been if the size of the study had been larger. Would you address what you calculated the power of the study would have had to be for those differences to be significant?

Dr. Bourgeois (Closing). I thank Dr. Sherrer for this thoughtful and considerate review. Regarding the use of hemoglobin A_{1c} as a monitor, as stated in the article, that is not really what we do. We monitor patients in day-to-day clinical settings according to blood glucose levels obtained by glucosemeters. Hemoglobin A_1 is primarily used in our clinic as an index because it is an attractive way to compare data. It is flawed but is simple, convenient, and avoids having to abstract large numbers of glucose determinations over long periods of time. In patient care it can be used as a cross-reference to glucose determinations that are done by the patients. I emphasize that we rely most heavily on the actual glucose determinations to assess ongoing control in a given patient.

Regarding the ability of chronic renal disease and bone marrow suppression to influence the values of hemoglobin A_{1c}, I would make two points. First, few of these patients had renal disease sufficient to cause bone marrow suppression in the first place. Second, since hemoglobin A_1 is expressed as a percentage of total, even if patients had anemia of chronic renal disease, hemoglobin A_1 levels would not be affected.

Regarding macrosomia, this may result more from less than ideal control and does not detract from the point that one can manage patients on the outside of the hospital as well as on the inside. As you are aware, the data supporting the notion that you can control macrosomia in diabetic patients simply by means of blood sugar control is mixed. I think that it is probably true that you can, but papers exist to support the notion that you cannot. Thus I believe the important point is that yes, some of these patients were less optimally controlled than we or you might desire them to be. That was not related to the outpatient setting but was related to the inability to control everybody as much as we want to.

We tried to lower our section rate compared with previous years but could not. However, our cesarean section rate in the worst of these patients was certainly no higher than is commonly reported even in well-controlled patients. I can cite one study of well-controlled diabetic patients managed preconceptually in which the cesarean section rate was still 50%.

Effectiveness of 1% lidocaine dorsal penile nerve block in infant circumcision

Robert M. Arnett, MD, J. Stephen Jones, MD, and Edgar O. Horger III, MD
Charleston, South Carolina

A prospective, controlled, double-blinded investigation was conducted to evaluate whether infants undergoing circumcisions with 1% lidocaine dorsal penile nerve blocks experienced decreased stress as compared with those receiving saline solution injections or no injections. Stress was measured in terms of pulse rate and oxygen saturation on a pulse oximeter. A subjective grading scale was also developed to measure infant irritability. The total number in the study was 51 with 23 infants in the lidocaine group, 21 in the saline solution group, and 7 in the no injection group. The results of the study revealed an average increase of 28.8% in the pulse rate above baseline for the control infants ($p < 0.001$) versus no significant change in the lidocaine group. The average oxygen saturation of the control groups decreased by 5.6% from baseline ($p < 0.001$), and that of the lidocaine group decreased by 1.0%, which was not a significant change. The subjective data were gained by using a grading scale of 1 to 6 with 1 being the least irritable infant and 6 being the most irritable infant. The physician evaluation gave an average rating of 4.2 to the control group versus 2.4 for the lidocaine group ($p < 0.001$). The nursing evaluation during the procedure gave an average rating of 4.2 to the control group versus 2.3 to the anesthetized group ($p < 0.001$). The subjective evaluation of infants before and after the procedure was not significantly different. There were no major complications in any of the groups. (Am J Obstet Gynecol 1990;163:1074-80.)

Key words: Circumcision, anesthesia, lidocaine

Infant circumcision, despite the controversy that surrounds it, still remains one of the most common surgical procedures performed in the United States. The rate of circumcision in this country is reported to range from 70% to 90% in newborn male infants, and it does not appear to be declining.[1-4] The American Academy of Pediatrics recently reviewed its stand on infant circumcision, and it now states circumcision may have several medical indications including a reduction in the rate of urinary tract infections and the incidence of penile cancer.[7] Given this background, it appears that circumcision will be around for some time to come. In many areas of the country the obstetrician is still the primary physician involved both in helping the parent make an informed decision and in performing the procedure itself.

For generations this procedure has been safely performed without anesthesia or analgesia. In 1978 Kirya and Werthmann[5] introduced their technique of using lidocaine with a dorsal penile nerve block and showed it to be both safe and effective in reducing pain. Several studies have shown the effectiveness of the dorsal penile nerve block in reducing infant stress,[3-5] but the procedure has still failed to gain wide acceptance. This study was designed to assess the effectiveness of dorsal penile nerve block in reducing infant stress through the use of a pulse oximeter to measure infant responses in terms of oxygen saturation and pulse rate. A subjective grading scale was used to measure the amount of infant irritability observed by both the nursing staff and the physician performing the procedure.

Material and methods

This study was approved by the Medical University of South Carolina Institutional Review Board for Human Research, and subjects were recruited into the study when the parents made a request to have their infant circumcised. Although no effort was made to encourage circumcision, all mothers were aware of its availability. Eighty-two percent of those who were asked to be in the study consented to participation and all signed an informed consent agreement.

Fifty-one infants from the low-risk newborn nursery at the Medical University of South Carolina participated in the study. Reasons for exclusion from the study included: gestational age < 36 weeks, weight < 2000 gm, brachial plexus injury, penile abnormality, Apgar score < 6 at 5 minutes, and suspected sepsis. The in-

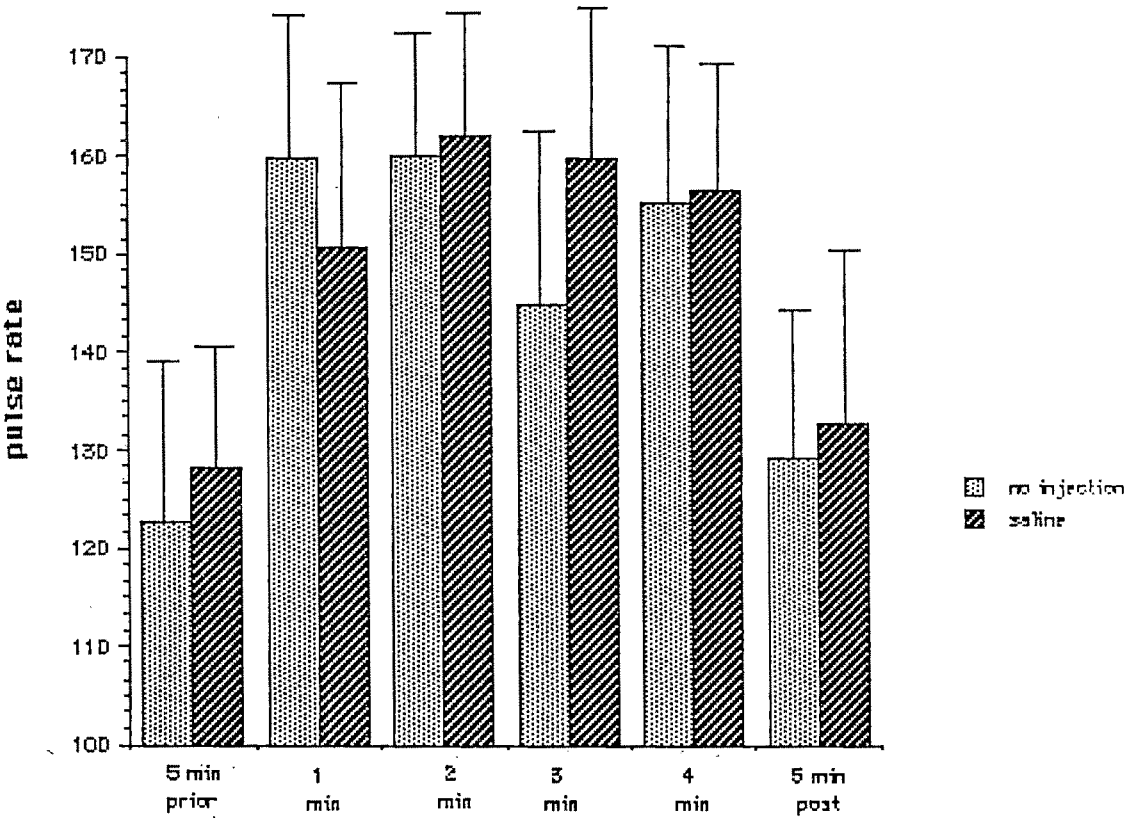

Fig. 1. Comparisons of pulse rate between saline solution group versus no injection group.

fants were divided by random selection through the use of cards into three groups. The first group (n = 23) received a 0.4 ml 1% lidocaine dorsal penile nerve block. The second group (n = 22) received 0.4 ml of normal saline solution in a similar fashion. The last group (n = 7) received no injections. The injections took place such that both the operator and the staff recording observations were blinded as to which infant was in which group. The average weight was 3208 ± 441 gm for the dorsal penile nerve block group versus the control groups 3304 ± 404 gm. The average gestational age of the dorsal penile nerve block group was 38.9 weeks versus 39.1 weeks in the controls. The average time since birth in the dorsal penile nerve block group was 26.0 hours versus 29.4 hours in the control groups. All infants were fasting for at least 90 minutes before the procedure, and they were monitored closely for aspiration throughout the procedure. The patients were placed on a standard circumcision board with extremities restrained. The pulse oximeter was attached to the right foot, and measurements were recorded as to the baseline heart rate and oxygen saturation in a noncrying state over 5 minutes. Measurements were taken at set 1-minute intervals during the procedure and at 5 minutes afterward.

All injection sites were prepped with alcohol, and injections were made in the manner described by Kirya and Werthmann[5] with placement at the base of the penis at the 10 and 2 o'clock positions and with a 26 gauge insulin syringe. The main difference in our technique and those described in previous studies was the use of 0.2 ml at each injection site as opposed to 0.4 ml. The injections were made in Buck's fascia approximately 2 to 3 mm from the skin surface with the physicians being careful to aspirate for blood before the injection. The penis was then prepped with povidone-iodine, and a standard Gomco Bell circumcision technique was used. Average circumcision time for both groups was 4.4 minutes. All infants were monitored for at least 2 hours afterward and urination was noted in all before discharge.

Initially, there were only two groups; one received a lidocaine injection and the other received saline solution. Some concern developed over whether injection of control saline solution could produce anesthesia, and a third arm was instituted in which a no injection control group was blinded by having the infant draped before the procedure. Seven patients were evaluated in this group, and comparisons with the saline solution group showed no significant changes in oxygen saturation or pulse rate between the two groups (see Figs. 1 and 2) with an unpaired Student t test. The results

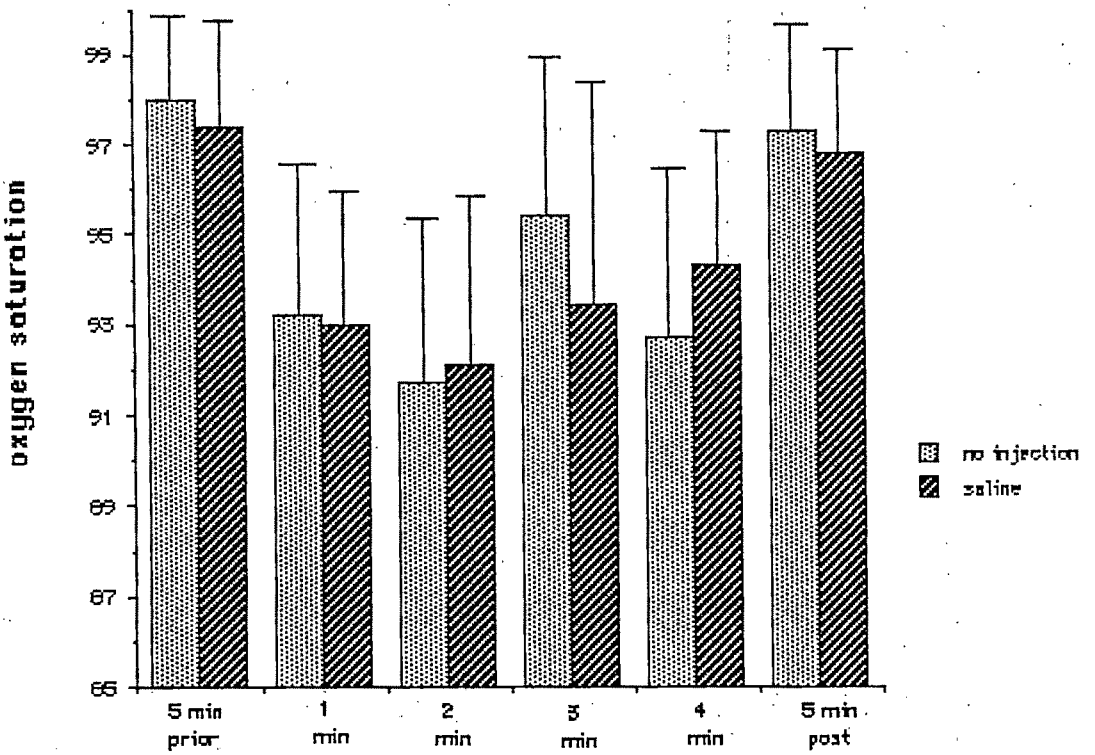

Fig. 2. Comparisons of oxygen saturation between saline solution group versus no injection group.

will show these two groups combined as one control group.

A subjective grading scale was developed and used by both the nursing staff observing the procedure and the surgeon performing the procedure. Infant irritability was graded on a scale of 1 to 6 with 1 representing the least crying or agitation and 6 the most. All nursing staff grading the procedure were experienced in newborn care and had observed multiple circumcisions. Ninety-one percent of the nursing evaluations were done by the same four senior members of the nursing staff. They were asked to grade the infant as to average irritability before the procedure, during the procedure, and 1 hour after the procedure. The surgeon was an obstetrics and gynecology resident experienced in circumcision, and he was asked to grade the infant's irritability during the procedure. He was also asked to assess whether he felt the infant was anesthetized. Eighty-five percent of the circumcisions were performed by the same senior resident. A second grading scale was used to assess bleeding from 1 to 3 with 1 being below average bleeding and 3 being above average. The surgeon was asked to use this scale during the procedure, and the nursing staff assessed the bleeding using this scale 1 hour after the procedure.

Results

Fig. 3 depicts the subjective grading results and shows that the physicians noted a significant difference in irritability during the procedure with the average being 4.2 ± 0.9 for the control group versus 2.4 ± 1.2 ($p < 0.001$ by unpaired Student t test). Physicians could correctly identify the anesthetized infant 81% of the time (17/21) and 100% of the infants that did not receive anesthesia were correctly identified. There was no significant difference in infant irritability noted between the groups by the nursing evaluation done before the procedure. Evaluation during the procedure showed an average of 4.2 ± 1.0 in the control group versus 2.3 ± 1.1 in the block group ($p < 0.001$ by unpaired Student t test). The postprocedure evaluation showed no statistical difference. The grading of both the bleeding during the procedure by the surgeon and the postprocedure evaluation by the nursing staff failed to show a statistical difference between the two groups. The control group was complicated by two episodes of postprocedural bleeding, one resolving with pressure and the other requiring suture. In the control group an infant also experienced one episode of emesis, which was easily resolved with suction. In the block group an infant experienced one episode of postprocedure bleeding, which stopped easily with pressure.

The pulse and oxygen saturation data were analyzed through the use of analysis of the variance with repeated measures between groups and over time. In this analysis any missing data points were estimated by using the group average at that evaluation time, thus giving an unbiased group error term. One member of each

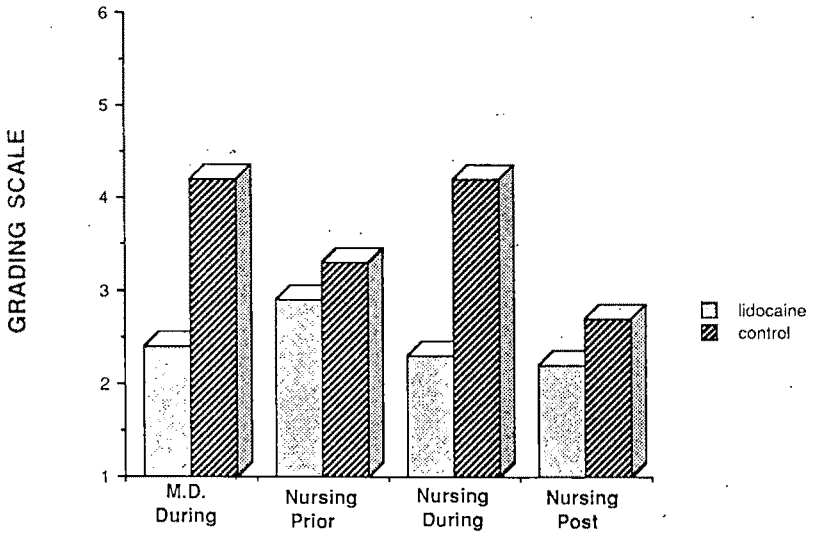

Fig. 3. Subjective grading of infant irritability.

group had multiple missing data points, and these were deleted from the analysis. The analysis documented a highly significant difference ($p < 0.001$) between the lidocaine and control groups in pulse rate and oxygen saturation. These differences were noted both between groups and over time.

Fig. 4 displays the comparison of the two groups' pulse rate during the study. The control group's average pulse rate rose 28.8% in a quadratic fashion from baseline, reaching a zenith at the 2-minute evaluation, and had returned to normal by the 5 minutes postprocedure evaluation. In the block group there was a very slight drop in the average pulse rate compared with baseline, this occurred in a skewed fashion. There was no significant difference found when the groups' baseline or 5 minutes postprocedure evaluations were compared.

Fig. 5 shows the comparison of oxygen saturation change in the two groups during the procedure. The control group showed a drop from a baseline average of 97.6 to a nadir of 92.2. The level then gradually rose to normal by the 5-minute postevaluation time; this occurred in a quadratic fashion. In contrast, the block group had a drop from 97.0 to a nadir of 96.0 with a gradual return to normal; this occurred in a skewed fashion. A comparison of the groups' baseline and 5-minute postprocedure evaluations showed no significant difference.

Comment

Circumcision has become part of United States social custom despite the controversy over whether there is truly an indication for its use. Given the recent change by the American Academy of Pediatrics on their stand against finding any indication for the procedure, I feel circumcision will continue being done at its present rate or even increase. Yet there seems to be little move to use penile nerve blocks, which have been proved through several studies to be safe and effective in the relief of the pain.[3-5]

This study has again demonstrated that lidocaine dorsal penile nerve block can effectively reduce the stress seen in infants undergoing circumcision. This study confirmed the data shown by Maxwell et al.[4] in 1987, that the oxygen saturation decrease typically seen with circumcision is significantly reduced through the use of a dorsal penile nerve block. Additionally, the rise in pulse rate typical in unanesthetized subjects also is prevented by penile nerve block. These changes have been documented in infants undergoing pain.[6, 8] The major difference in this study from the other data that have been previously presented is the use of less lidocaine to achieve the same response. We used 0.2 ml of lidocaine per injection site versus the 0.4 ml described by the other studies[3-5] and obtained similar findings.

Our subjective data also correlate with those found in studies by Stang et al.[3] and Kirya and Werthmann,[5] in that infants that undergo dorsal penile nerve blocks have less irritability during the procedure. The majority of the infants who have blocks will cry less and display less agitation than those without blocks. Physicians who performed the circumcision proved they could tell a difference in the infant's state by being correctly able to identify 81% of those infants anesthetized and 100% of those who were not, a finding previously reported by others.[4] This also points out that some blocks are unsuccessful and that some infants are going to be stressed from factors outside of the circumcision itself.

This study reiterates that this procedure is a simple, safe, and effective means of relieving the pain of circumcision. There have been a multitude of reasons given for why many physicians do not use this proce-

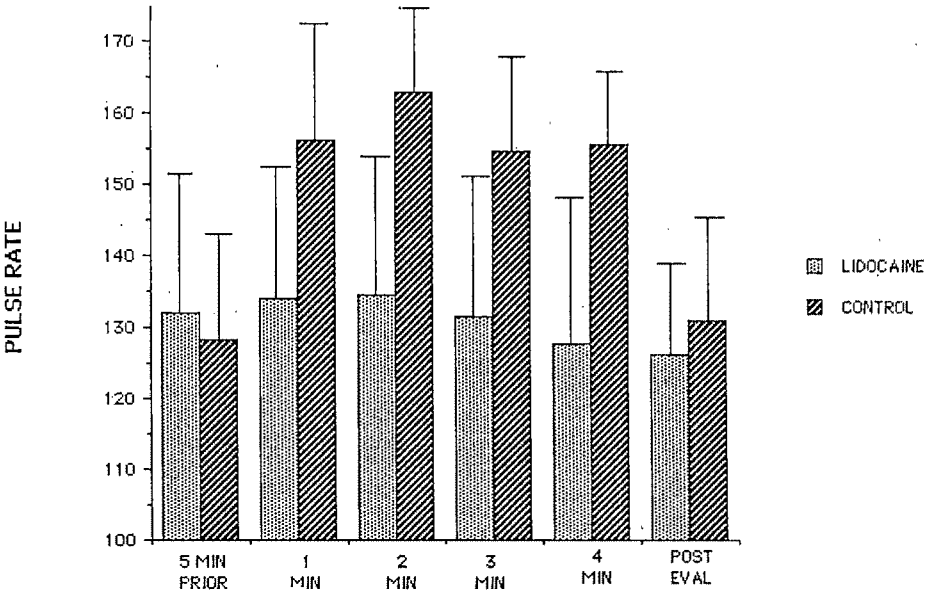

Fig. 4. Comparisons of pulse rate between control group versus lidocaine group.

dure, but surely we are building a large enough body of data to encourage its use and training throughout this country.

Editors' note: This manuscript was revised after these discussions were presented.

Discussion

Dr. Gene Burkett, Miami, Florida. Dr. Arnett and his colleagues have brought yet another study that endorses the efficacy of dorsal penile nerve block for circumcisions. Many other studies[1-3] in which dorsal penile nerve block was used for circumcision in newborns have shown reduction in pain, crying, agitation, and physiologic stress during the procedure. Prolonged agitation and reluctance to feed were minimal occurrences in dorsal penile nerve block circumcised newborns undergoing dorsal penile nerve block. On the other hand, if anesthesia was not used, heart rate rose by 34%, blood pressure by 15%, oxygen saturation decreased by 16%, and cortisol levels also were expectedly higher. With dorsal penile nerve block these side effects were markedly reduced statistically.

Despite this favorable situation, one survey[4] reported that only 23% of physicians used the technique of dorsal penile nerve block. Physicians who do not use the procedure are primarily under the guise: (1) that newborns do not feel intense pain during circumcision because of incomplete myelination of nerve pathways; (2) that immediate side effects are extremely shortlived, produce no long-lasting or residual deficits, and can be cushioned by tender loving care, (3) that dorsal penile nerve block itself adds pain and stress from the injection, together with the risks inherent in another step in the procedure.

Dr. Arnett and his colleagues are to be congratulated on this timely reminder that presents convincing data on the efficacy of dorsal penile nerve block in relieving intraoperative and postoperative irritability, pain, and tachycardia and in decreasing oxygen saturation. They report that when independent blinded observers (physicians and nurses) used grading scales of infant irritability, neonates with dorsal penile nerve block had significantly lower scores (less irritability) than the control group. Unfortunately the rating scale for irritability was omitted from the manuscript; had it been included,

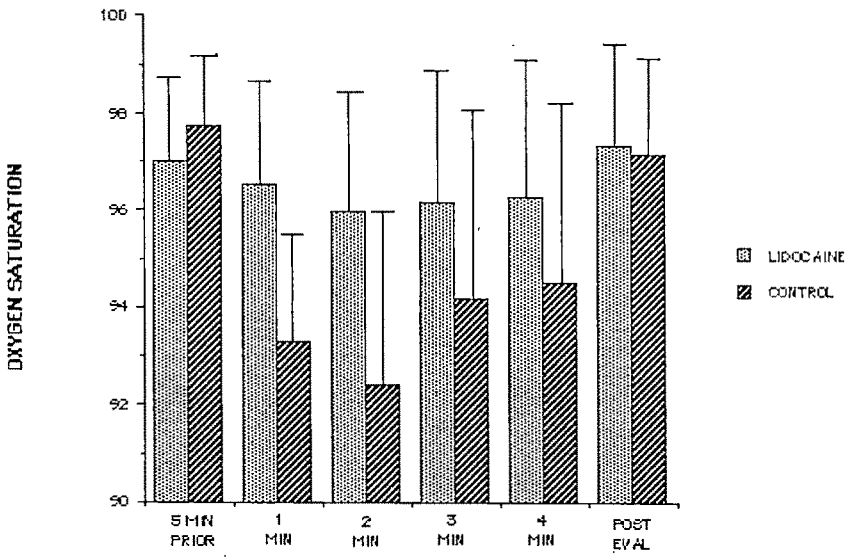

Fig. 5. Comparisons of oxygen saturation between control group versus lidocaine group.

it would have facilitated a more direct evaluation to the conclusions of the study.

Intraoperatively, oxygen saturation showed a greater decrease in the infants without block. A return to a normal level occurs by 5 minutes after operation. The authors did not explore the significance of this finding. At what time does the nadir occur and how long does it last? Are there any harmful effects produced by this change in oxygen saturation?

Perhaps, too, Dr. Arnett should have included data on irritability, pulse, and oxygen saturation *immediately* after injection and before circumcision. Since these authors recorded scores at 1-minute intervals, these data are available and their inclusion in the report would define the effect of the injection itself, a problem raised by nonusers of dorsal penile nerve block.

Another area of concern is the study groups. Initially, Dr. Arnett and colleagues started with two groups—one received lidocaine and the other saline solution injections. When concern "over whether control saline could produce anesthesia" arose, the investigators subdivided the saline control group and reported on seven neonates in whom no injection was used. This changed the study design, as well as the control group, and weakened the statistical power[5] of the conclusions. From this perspective no valid conclusions can be made, especially on the noninjected neonates. A larger number of noninjected neonates should be studied separately as a third group in the original concept.

The differences between the lidocaine group and the remaining saline solution group, 23 in total, are, however, sufficient enough to indicate trends strong enough to support the efficacy of the dorsal penile nerve block.

Even using 0.2 ml of lidocaine at each site, half of the dose recommended in other studies, Dr. Arnett and associates have shown us a simple, easy, effective method of controlling pain and irritability without increasing the overall complication rate of circumcisions, reportedly 0.2% to 0.6%. Perhaps the real question to be put is not whether we should be routinely using dorsal penile nerve block but rather whether proper genital hygiene would effectively reduce urinary infections in the uncircumcised infant. The American Academy of Pediatrics[6] in its concern for an increased incidence of urinary tract infections among uncircumcised infants, emphasized that mothers of newborns should be advised of this recent finding as an important part of the decision-making process for circumcision. Notwithstanding this new position, the message from Dr. Arnett and colleagues is that the procedure can be performed safely and humanely. The crying, agitated newborn is indeed in pain, with dorsal penile nerve block, there is no longer an excuse not to relieve that agony. We thank them for that rejoinder.

Dr. David Soper, Richmond, Virginia. Did you consider using infants who were not circumcised at all as a control group? Second, subjective scales by their nature cannot really be considered continuous data. Probably a more appropriate statistical test would be the Mann-Whitney V test.

Dr. Frank Greiss, Mooresville, North Carolina. Dr. Arnett, I think Dr. Burkett asked this question, but I will ask it again. Did you actually look at the parameters before and while you were doing the nerve block itself? Would you describe for me who trained your residents to do circumcisions at the Medical University of South Carolina, and what sort of a formal process do you go through to do this?

Dr. John W. C. Johnson, Gainesville, Florida. I want to congratulate you, Dr. Arnett, on a nice study. It was one that needed to be done. I was very curious about the drop in oxygen saturation. Do you have an explanation for that?

Dr. Arnett (Closing). The grading scale is something that was added on. I was actually just going to measure pulse rate and oxygen saturation, and then I thought a scale would not be a bad thing to look at. We really did not put as much attention into our scale as we should have, and I am not sure what that data really mean. They definitely show that people could tell a difference even with a very widely subjective scale.

We did have some data right after the injections took place. Looking at what happened to oxygen saturation and crying, on average, they resolved in 30 seconds after the injection. Obviously some infants cried more than others, but on an average the pulse returned to normal and the oxygen saturation returned to normal very quickly. We did determine these on the first 35 patients that we had in the study, but I did not present those data.

Regarding Dr. Greiss' question on how we were trained, our residents in the first-year level are generally taught by the senior residents. Our first-year residents go in with the senior residents and learn to do circumcisions under their guidance. When we feel they are performing them on a level that we can leave them alone, we do. This generally is in the first few months. We are not teaching the block to residents as a manner of routine, but I encourage them to use it and teach my technique when requested.

Finally, regarding the drop in oxygen saturation, there have been several studies by anesthesiologists showing any infant under stress can undergo a drop in oxygen saturation. I am sure that this is what is happening when the baby cries or is under a certain amount of stress; the oxygen saturation typically drops a certain degree.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1990 issues from the Publisher, at a cost of $56.00 ($79.00 international) for Vol. 162 (January-June) and Vol. 163 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318, USA; phone (800) 325-4177, ext. 7351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Reducing cesarean sections at a teaching hospital

Luis Sanchez-Ramos, MD,[a] Andrew M. Kaunitz, MD,[a] Herbert B. Peterson, MD,[b] Beverly Martinez-Schnell, PhD,[b] and Robert J. Thompson, MD[a]

Jacksonville, Florida, and Atlanta, Georgia

A department-wide effort to reduce the cesarean section rate at the University Medical Center of Jacksonville (Florida) began in 1987. University Medical Center, a teaching hospital with approximately 4500 annual deliveries, serves an almost exclusively indigent obstetric population. Overall, the cesarean section rate declined from 28 per 100 deliveries in 1986 to 11 per 100 in 1989. Decreasing the number of repeat cesarean sections played an important role in reducing total cesarean deliveries. In 1986 32% of women with prior cesarean sections underwent a trial of labor. By 1989 this proportion had increased to 84%. In 1986 65% of women undergoing a trial of labor were delivered vaginally. By 1989 this proportion had increased to 83%. For these reasons the proportion of patients who had repeat cesarean sections dropped from 8% in 1986 to 3% in 1989. Changing approaches to the evaluation and management of dystocia and fetal distress also helped to lower the overall cesarean section rate. In 1986 cesarean sections for at least one of these two indications accounted for 14% of all deliveries. By 1989 this percentage had dropped to 4%. Because selective criteria for vaginal delivery of fetuses in breech presentation were maintained, incremental increased rates of vaginal breech delivery had only a minimal impact on lower overall cesarean section rates. The reduction in the number of cesarean sections was accomplished without compromising neonatal outcomes. In fact, during this 4-year period neonatal mortality rates actually decreased; neonatal morbidity rates remained stable. Our experience suggests that cesarean section rates can be substantially reduced without compromising the newborn. (Am J Obstet Gynecol 1990;163:1081-8.)

Key words: Cesarean section, perinatal outcome, trial of labor

In the United States the rate of cesarean sections has quintupled from 5% of obstetric deliveries in 1964 to greater than 25% in 1988.[1] Some have suggested that this increase in cesarean deliveries has played a major role in lowering neonatal mortality.[2] Others note the negative impact high cesarean rates have on maternal health[3, 4] and obstetric care costs.[5] Although a broad consensus agrees that current rates of cesarean section are excessive, the number of such deliveries remains high. This article describes efforts to reduce cesarean sections at a teaching hospital.

Material and methods

University Medical Center of Jacksonville, one of 10 regional perinatal centers in Florida, serves a largely high-risk, low-income obstetric population. All obstetric patients are cared for by resident physicians in obstetrics and gynecology and nurse-midwives supervised by full time faculty members.

Beginning on July 1, 1987, a recently hired faculty perinatologist (L.S.R.) introduced new guidelines regarding intrapartum management of women with prior cesarean sections. Patients with one or two previous cesarean sections were counseled regarding the benefits of trial of labor. Patients with low transverse and vertical scars not extending into the uterine corpus were considered candidates for trial of labor. Patients with either a previous classic cesarean section, myomectomy in which the uterine cavity had been entered, or previous uterine incisions of unknown type were not considered candidates for vaginal delivery. The option of electing a repeat cesarean section was not routinely offered to patients who otherwise were appropriate candidates for trial of labor. Patients with prior cesarean section(s) who requested postpartum sterilization likewise were not routinely offered a cesarean section.

The intrapartum management of the patients undergoing a trial of labor included continuous electronic fetal monitoring. After rupture of membranes an intrauterine pressure catheter and fetal scalp electrode were applied. As for other intrapartum patients, oxy-

tocin for induction and augmentation or both and epidural anesthesia were used.

New guidelines for performing primary cesarean section were also established in July, 1987; these considered dystocia, fetal distress, and fetal malposition as potential indications. Dystocia was diagnosed according to the criteria outlined by Friedman.[6] Cesarean delivery for arrested dilatation was performed after no further dilatation was noted with more than 2 hours of regular uterine contractions (≥150 Montevideo units), whether contractions occurred spontaneously or as a result of oxytocin augmentation. Other diagnoses classified as arrest disorders were prolonged deceleration phase (>3 hours for nulliparous women and ≥1 hour for multiparous patients), and arrest of descent (no progression in descent for more than 1 hour for nulliparous women or for more than 30 minutes for multiparous women) during the second stage of labor.[7] In cases of arrest of dilatation as a result of a hypocontractile pattern, cesarean section was performed only if at least 4 hours of contractions achieved with oxytocin failed to progress labor. Medically indicated induction of labor in patients with unfavorable cervices was preceded by cervical ripening with either prostaglandin gel (4 mg of Prostin E_2, The Upjohn Co., Kalamazoo, in 6 ml of sterile lubricant) or Hypan (Dilapan, Gynotech Inc., Lebanon, N.J.) osmotic dilators.[8, 9]

Fetal distress suggested by electronic fetal monitoring was confirmed by scalp pH sampling. When the extent of cervical dilatation did not permit scalp sampling, fetal acoustic stimulation was performed.[10] A rise of 15 beats/min above the fetal heart rate baseline for a duration of at least 15 seconds was considered reassuring.

Vaginal delivery of breech fetuses was performed only if the following criteria were met: (1) frank or complete breech presentation; (2) adequate x-ray pelvimetry without hyperextension of the fetal head; (3) ultrasonographically estimated fetal weight between 2500 and 4000 gm; and (4) presence of an obstetrician with experience in breech deliveries. For patients with singleton gestations between 36 and 39 weeks in which the breech presentation was identified antepartum, external cephalic version was attempted. Twin pregnancies with a nonvertex second twin were managed according to the criteria of Chervenak et al.[11] After the birth of the first twin, external cephalic version was attempted if the second twin was not vertex. If the version was not successful and the estimated fetal weight was ≥2000 gm, a cesarean section was performed after failed version.

At weekly conferences, departmental resident and obstetric faculty physicians reviewed each cesarean section and focused on indications for abdominal delivery. Particular attention was paid to electronic fetal monitoring records, umbilical cord gas results, and Apgar scores. In autumn of 1989 a sustained decline in the overall cesarean section rate was noted by the faculty at University Medical Center. For this reason it was decided to scrutinize neonatal morbidity and mortality while continuing to monitor cesarean section trends. This article documents the impact of changing clinical intrapartum management policies.

We computed annual proportions of primary and repeat cesarean sections from 1986 to 1989. For each year, primary sections were classified by indication. We tested the difference between the proportions in 1986 and 1989 for statistical significance.[12] Similar tests for difference were performed for the proportion of trial of labor among women with prior cesarean section, the proportion of vaginal birth among women undergoing a trial of labor, the neonatal and perinatal mortality rates, and adverse neonatal outcome rates. During the same years (1986 to 1989), cesarean section rates, neonatal intensive care unit admission rates, and neonatal mortality rates were tested for difference in each of five birth weight categories.

Results

Cesarean sections. The overall cesarean rate decreased steadily from 27.5% of deliveries in 1986 to 10.5% in 1989 ($p < 0.0001$) (Table I). Decreased rates of cesarean section occurred among women who had infants in all birth weight categories; these decreases were statistically significant for all categories except for women who had infants weighing >4500 gm (Fig. 1). The rates of primary cesarean sections fell from 19.5%

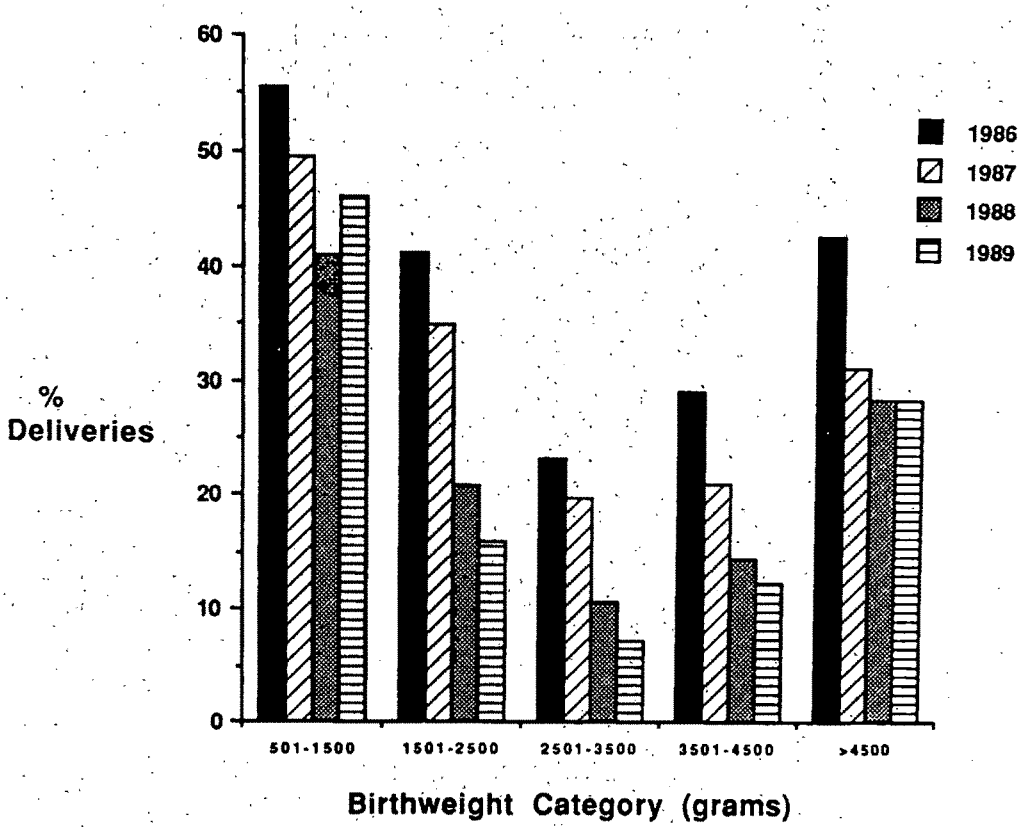

Fig. 1. Birth-weight-specific cesarean section rates, 1986 to 1989.

Table II. Deliveries of women with prior cesarean section, University Medical Center, Jacksonville, 1986 to 1989

	1986		*1987*		*1988*		*1989*		*Difference (1989-1986)*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*	*%*	*p Value*
TOL	139	31.7	193	41.9	381	76.5	487	83.9	52.2	$p < 0.0001$
Proportion of women undergoing TOL with subsequent vaginal birth	90	64.7	142	73.6	342	85.0	403	82.7	18.0	$p < 0.0001$
Proportion of all women delivered after prior cesarean with subsequent vaginal birth	90	20.5	142	30.8	342	65.1	403	69.4	48.9	$p < 0.0001$

TOL, Trial of labor among women with prior cesarean sections.

to 7.2% ($p < 0.0001$), whereas repeat cesarean sections declined from 8.0% to 3.3% ($p < 0.0001$). While rates of cesarean sections decreased, operative vaginal deliveries (forceps and vacuum) remained stable (16.2% of all vaginal deliveries in 1986 versus 18.5% in 1989).

Decreased repeat cesarean sections played a key role in the overall reduction in cesarean deliveries. From 1986 to 1989 the proportion of patients with prior cesarean deliveries who underwent a trial of labor increased from 32% to 84% ($p < 0.0001$). During these same years the proportion of women undergoing a trial of labor who had subsequent vaginal births increased from 65% to 83% ($p < 0.0001$). Among all women who were delivered after a previous cesarean section, the percentage who had a subsequent vaginal birth increased from 20.5% to 69.4% ($p < 0.0001$) (Table II).

Decreased rates of cesarean section for dystocia and fetal distress also contributed to overall reduction in cesarean delivery. From 1986 to 1989 rates of primary cesarean section for dystocia declined from 7.2% to 2.9% ($p < 0.0001$) and for fetal distress from 6.7% to 1.5% ($p < 0.0001$) of all deliveries (Table III). Cesarean

Table IV. Perinatal and neonatal mortality, University Medical Center, Jacksonville, 1986 to 1989

	1986	1987	1988	1989	Difference, 1989-1986	
					%	p Value
Neonatal deaths	71	41	35	33		
Fetal deaths	67	43	43	44		
Live births (denominator)	4336	4270	4470	5157		
Neonatal mortality rate*	16.4	9.6	7.8	6.4	−10.0	$p < 0.001$
Perinatal mortality rate†	31.8	19.7	17.4	14.9	−17.4	$p < 0.0001$

*Based on deaths occurring at <28 days of life per 1000 live births.
†Fetal deaths plus neonatal deaths per 1000 births.

section for breech and other fetal malpresentations decreased from 3.0% to 2.1% of deliveries during the years 1986 through 1989, which represented a small but statistically significant change.

Perinatal outcome. Overall, the perinatal mortality rate decreased from 31.8 in 1986 to 14.9 in 1989 ($p < 0.0001$), whereas the neonatal mortality rate decreased from 16.4 to 6.4 ($p < 0.0001$) (Table IV). Birthweight-specific neonatal mortality declined in infants weighing <2500 gm, and rates remained stable in higher-birth-weight categories (Fig. 2). Because the number of neonatal deaths in each category was small, the decrease was not statistically significant.

The incidence of low 1- and 5-minute Apgar scores and neonatal seizures remained stable over the 3-year study period. During these years no consistent trends were observed in either incidence of neonatal intensive care unit admissions or length of neonatal intensive care unit stay. In 1989 there was a statistically significant reduction in the proportion of newborns admitted to the neonatal intensive care unit (Table V, Fig. 3).

Comment

Elimination of elective repeat cesareans, active management of dystocia, and an approach to suspected fetal distress that emphasized intrapartum confirmation contributed to the reduction of overall cesarean sections at University Medical Center from 1986 to 1989. Of all women who were delivered after a previous cesarean section, 69% had subsequent vaginal births in 1989; the comparable U.S. national estimate for 1987 was 9.8%.[13]

Our approach to trial of labor after prior cesarean is based on two assumptions. First, trial of labor after one or two prior cesarean sections in which uterine incision(s) involved only the lower segment is safe.[14, 15] Second, higher morbidity and health care costs[1] of elective repeat cesarean section outweigh the advantages that individual patients or their obstetricians may perceive.

Active management of dystocia, as described earlier in this report, also played an important role in reducing the number of cesarean sections at our institution. Similar intrapartum protocols have resulted in lower rates of cesarean section for dystocia in other institutions. Myers and Gleicher[16] were able to reduce their cesarean section rate from 17.5% to 11.5%. Porreco[17] demonstrated that a low cesarean section rate (6%) can be achieved without compromising neonatal outcome. Similarly, reports from Ireland[18] have consistently documented a very low cesarean section rate (4% to 6%) without undue perinatal morbidity or mortality.

Our approach to cesarean section for fetal distress emphasized fetal scalp pH testing when feasible to improve the precision of this diagnosis. This strategy acknowledges the low positive predictive value of electronic fetal monitoring as a sole indicator of fetal distress.[19]

Because selective criteria for vaginal delivery of fetuses in breech presentation were maintained, incremental increased rates of vaginal breech delivery had only a minimal impact on lowering overall cesarean section rates at University Medical Center. In a report of another program to lower the number of cesarean sections, a liberalized approach to vaginal breech delivery was associated with three neonatal deaths among breech presentation fetuses.[16] Some authorities have criticized this liberalized approach to vaginal breech delivery.[20, 21] We support maintenance of selective criteria for vaginal delivery of breech presentation fetuses,

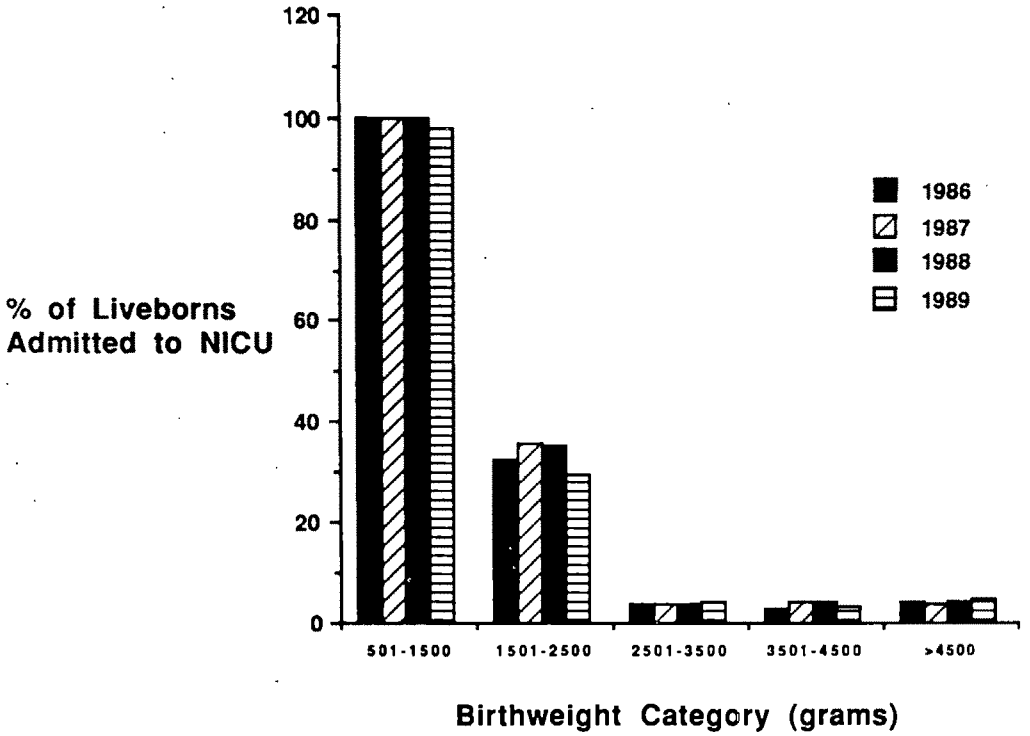

Fig. 3. Birth-weight-specific neonatal intensive care unit admissions, 1986 to 1989.

and also underscore that the number of cesarean sections can be substantially reduced without major alterations in managing obstetric malpresentations.

Our finding that perinatal and neonatal mortality rates decreased concurrently as the number of deliveries decreased should not be overinterpreted. These declines in mortality rates could well be attributable to factors other than method of delivery. Data from the National Infant Surveillance project (unpublished) found higher mortality rates for those infants weighing ≥1000 gm delivered by cesarean section. Although we believe our data strongly suggest that reductions in cesarean section can be accomplished without increasing risk to infants, only a randomized clinical trial could test that hypothesis.

Our success in lowering cesarean section rates is largely attributable to our centralized approach to intrapartum decision making. Although others have used such a centralized approach successfully,[18] it contrasts with other approaches many obstetric units in this country use, in which cesarean section rates for individual obstetricians may vary markedly. Goyert et al.[22] noted that rates of cesarean delivery for different physicians at a community hospital serving an affluent population ranged from 19% to 42%. Their analysis suggested that the individual clinician's practice style itself was a major determinant of the wide variations in rates of cesarean section. Implementing standardized protocols regarding repeat cesarean sections, dystocia, and fetal distress requires substantial commitment and effort from obstetricians and others who care for obstetric patients. However, our experience suggests that such an effort can substantially reduce rates of cesarean delivery without compromising the newborn.

Addendum

During the first 6 months of 1990, the overall cesarean section rate has continued to decrease (8.6%), without an evident increase in perinatal morbidity and mortality.

Discussion

DR. ROBERT G. BRAME, Greensboro, North Carolina. This article covers an obviously timely topic. Despite much that has already been written, the continuing appropriateness of the topic results from the great disparity that persists in actual practice compared with a now abundant literature that suggests that the cesarean section rate is too high. This report documents the achievement of a very low cesarean section rate in an indigent and high-risk population, with a reduction in the combined section rate from 27% in 1986 to 11% in 1989, with an attendant reduction in perinatal and neonatal mortality rates; this is principal point of the article. The authors demonstrate quite clearly that a dedicated (and if I may read between the lines) intense effort to reduce the cesarean section rate can be successful. By the standard measures we use perinatal morbidity seems to certainly be no worse, but this is obviously a much more difficult assessment to make. I commend the authors for this excellent work but I do have some questions.

Although you emphasize that elimination of elective "repeat cesarean sections played a key role in the overall reduction in cesarean deliveries," I note that, according to Table I, the reduction in primary cesarean section almost exactly duplicated the reduction in repeat sections; I am a bit puzzled by this emphasis. Since you do not give patients with previous cesarean sections the option of a repeat cesarean delivery, I would like to know what you tell them. Do you have patients who demand a repeat cesarean section, and what do you do with them? I suspect my patients are similar to yours, and I have some patients for whom no amount of education or paternalism will convince the patient that she should be delivered vaginally. In addition, I have problems dealing with unfavorable and unengaged postdate pregnancies, labor in patients with previous section with unengaged fetal parts, and excessively large fetuses that are unengaged; these situations balloon my cesarean section rates. I wonder if you have ways of dealing with these circumstances that might help us.

Finally, although the last word on this topic has obviously not been written, cesarean section rates *can* be reduced, but to what degree this is really in the best interest of patients is not quite so clear. I spent most of my adult life adjusting to a belief that cesarean section was all right, and now I am trying to adjust to your implied suggestion that I may be performing too many cesarean sections. I do not know what the section rate ought to be. I do know, as a practitioner, that the decision to perform or not perform a section, particularly in a private, well-educated population, is rarely a simple matter of strict medical indication. In conclusion, we obviously can reduce the cesarean section rate, and the best scientific information suggests we can do that safely and that we ought to try. This presentation is an excellent documentation that a reduction can be achieved and I congratulate the authors on this effort. Yet to be answered, however, is the question encompassing all of those other considerations that enter into a decision: our legal climate, patient autonomy versus medical paternalism, and desire by patients and doctors to control events and their timing by surgical delivery.

DR. WILLIAM KIRKLEY, Fort Lauderdale, Florida. I have several questions. Did you have any patients with ruptured uteri? I presume you did not since you did not mention it. Second, when I was practicing obstetrics and the fetal heart monitor strip would be slightly abnormal or moderately abnormal, I would rush to do a cesarean section. I am sure you have had similar cases in your hospital. Do you rely solely on the fetal scalp pH? Third, do you have any potential lawsuits regarding these cases? If you have a monitoring problem during labor, you will be sued if you do not take action immediately.

DR. WILLIAM S. GRIZZARD, JR., Petersburg, Virginia. Do you allow patients with either twin pregnancy or breech presentation to undergo a trial of labor?

DR. HUGH RANDALL, Atlanta, Georgia. This article suggests the need for an individual, if not a committee, within the hospital to scrutinize cesarean sections. I know that in our community cesarean section rates around 35% are common. When there are individuals

like Dr. Sanchez-Ramos to study these services and to perform the type of peer review that was done at this institution, I think we will really be able to reduce the cesarean section rate. In many cases his review perhaps made him an unpopular individual. I would ask Dr. Sanchez-Ramos how many times he or his committee had to point out to a physician that he had not met the criteria for doing the cesarean section, for example, for dystocia?

DR. SAMIR BEYDOUN, Miami, Florida. You emphasized that there is no increase in the neonatal morbidity and mortality. I would like to ask Dr. Sanchez-Ramos to compare the maternal morbidity in cases with failed trials of labor that ultimately needed a repeat cesarean section and those with elective repeat cesarean section.

DR. GENE BURKETT, Miami, Florida. In Miami we have a large migrant population. How do you handle cases with unknown scars?

DR. SANCHEZ-RAMOS (Closing). First, I will address Dr. Brame's concern about not giving our patients a choice between repeat cesarean sections and a trial of labor. In accord with recommendations of the American College of Obstetricians and Gynecologists, we do not routinely perform elective repeat cesarean sections. We believe that vaginal birth after cesarean section is a much safer procedure than a repeat cesarean section. There are currently no reports in the literature of maternal deaths directly attributable to vaginal births after cesarean sections. In contrast, maternal deaths as a result of repeat cesarean sections do occur.

Dr. Kirkley had a question regarding ruptured uteri. I am not aware of a true ruptured uterus occurring in a patient with a previous cesarean section undergoing a trial of labor. Occasionally we have noted "windows" or dehiscences. The most serious dehiscence that I recall was in a patient with a previous low vertical scar who was undergoing an elective repeat cesarean.

With regard to the use of scalp pH sampling and electronic fetal monitoring, we use the former to complement the latter. Rather than rely solely on scalp pH results or alterations in the fetal monitoring tracing, we use both modalities together.

I am unaware of any lawsuits directly related to our management protocol for cesarean sections.

With regard to management of twins we currently allow patients with twins and previous cesarean sections a trial of labor.

Peer review has been one of the most important factors contributing to the reduction of cesarean sections at our hospital. All our practicing obstetricans are full-time faculty members. We do not have private practitioners. All the cases discussed at our cesarean section review meetings are those performed by the residents under faculty supervision; critiquing of individual cases is therefore facilitated. I may occasionally become unpopular if a resident feels he or she is not performing enough cesarean sections. However, the peer review process itself has not generated hard feelings. I am popular with the pediatric physician and nursing staff because our intrapartum policies have markedly reduced their visits to the operating room.

We did not address maternal morbidity in our study. However, it is well accepted that less morbidity occurs in patients who are delivered vaginally compared with those delivered by cesarean sections. Because of the reduction of almost 2000 cesarean sections during the past 3 years, we think that the decrease in post-cesarean section endomyometritis has substantially reduced overall maternal morbidity.

What do we do with patients with unknown scars? We have had patients from as far away as Nigeria whose medical records were more available that those of our local patients. It is embarrassing to note that the most difficult records to find are those from our own institution. When we first started with an aggressive approach to vaginal birth after cesarean section, patients with unknown scars were not allowed a trial of labor. Currently, we try to individualize management in these cases. We try to obtain a history as to the indication for the previous section. If the indication appeared to be an arrest of dilation at 8 cm (for example), then we conclude that the patient probably had a low transverse incision and therefore may proceed with a trial of labor.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146-3318 USA; phone (314) 872-8370, ext. 7394. In the U.S., call toll-free: 1-800-325-4177, ext. 7394. Please allow six weeks for delivery.

LETTERS TO THE EDITORS

HELLP does not always mean immediate HELP!

To the Editors: Dr. Sibai has presented his views on the HELLP syndrome (Sibai BM. The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? AM J OBSTET GYNECOL 1990; 162:311-6). I argue that the disease presents in several patterns (A, B, C, . . .).[1] In my experience Native Americans and Hispanics have more liver involvement, blacks have more hypertension, and whites more thrombocytopenia. Definitions of the severity of HELLP syndrome according to absolute laboratory values will fail unless the ethnic background and disease pattern are considered.

After the introduction of screening laboratory tests in the mid 1960s, gravid women with unexpected elevated liver enzymes (serum glutamic oxaloacetic transaminase) and without severe hypertension were often treated as if they had viral hepatitis. Therapy was bed rest, diet, and isolation. Although "fulminating hepatitis" (probably HELLP) rarely developed in a patient, the majority did well. My article describing gravid women with no hypertension or mild hypertension, elevated liver enzymes, and thrombocytopenia as having preeclampsia was finally published after multiple changes of titles and with expansion of topics.[1] The pendulum then immediately swung to considering these same cases as having severe preeclampsia.[3] I have since seen patients who have been misdiagnosed in haste as having HELLP syndrome who in retrospect were seriously ill from idiopathic thrombocytopenia purpura, thrombotic thrombocytopenic purpura, or systemic lupus. Early delivery did not benefit them or their premature newborns.

I can find no evidence that maternal mortality or morbidity has improved since the introduction of the eponym "HELLP." I further believe that a diagnosis of HELLP syndrome is now a significant cause of iatrogenic prematurity and that many such patients <28 weeks' gestation should receive a trial of conservative (radical?) therapy. Dr. Sibai suggests that those who respond to plasma volume expansion, steroids, (aspirin), and bed rest are "without 'true HELLP' syndrome." I disagree. However, if calling the disease process "false HELLP" is necessary to achieve 1 to 2 extra weeks of intrauterine life, then false HELLP is a better term than all those I have tried.[1, 2-4]

The obstetrician's first duty is to the mother, but to burden the nursery and society with 25- to 28-week newborns on the premise that the mother with toxemia and laboratory abnormalities may be very ill[5] should be seriously debated.

Reply

To the Editors: I thank Dr. Goodlin for his interest and comments regarding my article. This Clinical Opinion was designed to highlight some of the problems encountered in the diagnosis and management of this syndrome. Our patient population is either black or white; most patients with this syndrome are white. None of our patients are native Americans or Hispanics. Thus the ethnic background was considered in this report.

The reason that maternal mortality and morbidity has not improved is mainly related to failure to diagnose the disease and deliver the patient when appropriate.

Dr. Goodlin recommends conservative (radical?) therapy for patients with probable HELLP syndrome at 25 to 28 weeks' gestation. Our review of the literature and our data do not support benefit or the safety from such an approach. If such data are available, we encourage Dr. Goodlin to share this experience with the readers for the benefit of all. Until such data are published, I will continue to caution against conservative management in patients with true HELLP syndrome as described in my report.

Phenytoin and magnesium sulfate in eclampsia

To the Editors: In a recent excellent study on the use of intravenous phenytoin in severe preeclampsia (Ryan G, Lange IR, Naugler MA. Clinical experience with phenytoin prophylaxis in severe preeclampsia. AM J OBSTET GYNECOL 1989;161:1297-304), the authors suggest that this regimen may be effective in preventing eclampsia.

The results of our recent study[1] comparing the efficacy of phenytoin and intravenous magnesium sulfate in 22 cases of eclampsia do not support this statement.

None of the 11 patients managed with magnesium sulfate had further convulsions, whereas four of the 11 patients treated with phenytoin sodium had further convulsions despite therapeutic blood levels and were subsequently effectively treated with magnesium sulfate.

I would therefore suggest that the use of phenytoin in severe preeclampsia is not justified if this drug failed

to prevent further convulsions in four of 11 patients with eclampsia.

The indication for and the effectiveness of anticonvulsant therapy in the management of severe gestational proteinuric hypertension (preeclampsia) is unproved, and Redman[2] has stated that in most cases control of the hypertension and termination of the pregnancy will resolve the condition. This issue should be resolved by a large random control study.

J. Dommisse, FRCOG

Department of Obstetrics and Gynaecology, University of Cape Town, Cape Town, South Africa

Reply

To the Editors: I welcome Prof. Dommisse's comments and I have read his recent article with great interest.[1] I acknowledge his concerns; however, for the following reasons I cannot agree with his conclusion that the use of phenytoin in severe preeclampsia is unjustified.

There will always be the occasional patient who has seizures regardless of the anticonvulsant used. This in itself is not reason enough to abandon that medication completely. Recurrent convulsions are reported in 26% of eclamptic patients who receive diazepam.[2] Treatment failures have also been reported with magnesium sulfate; seizures have occurred in 1% to 3% of patients despite therapeutic doses of magnesium sulfate.[3, 4] These reports stem from areas where magnesium sulfate is used quite liberally (9% of deliveries); thus the actual incidence of treatment failures in truly severe cases of preeclampsia may be much higher. Of more significance is the fact that 12% to 37% of cases of eclampsia occur in patients already receiving magnesium sulfate.[2, 4-6] In his own article Prof. Dommisse admits to a 3% incidence of recurrent convulsions in patients receiving magnesium sulfate in his institution.

The primary objection to use of magnesium sulfate is that it is unable to cross an intact blood-brain barrier and therefore has no central protective effect. Sibai et al.[7] have shown that the abnormal electroencephalographic pattern in eclampsia is unaffected by use of magnesium sulfate. An abnormal seizure pattern persists centrally despite the absence of any peripheral manifestation of a seizure, which is exactly what would be expected with the administration of a neuromuscular blocker such as magnesium sulfate.

Unlike status epilepticus,[8] almost all maternal mortality in eclampsia can be attributed directly to the cerebral manifestations of uncontrolled hypertension.[9-11] It has been suggested that aggressive management of hypertensive episodes is the key to prevention of seizures.[12, 13] The upper limit of cerebral autoregulation varies from individual to individual; thus we cannot set a universal level above which hypertension should be treated. It is possible that this may have been a significant element in several of the "phenytoin failures" described, especially since hypertension was not treated until it had reached a level of 115 mm Hg diastolic pressure.

I would be interested in further information regarding the patients in Prof. Dommisse's study who had recurrent seizures. This includes the timing of seizures in relation to the administration of clonazepam, the serum albumin levels, the levels of blood pressure compared with the other patients, and whether any other form of therapy, apart from magnesium sulfate, was given at the time of recurrence. I think the results of the neurologic investigation of these patients would also be enlightening, particularly with respect to diagnostic imaging and electroencephalographic studies. Most patients had already had multiple seizures before any therapy was given.

Our pharmacokinetic data would support his conclusion that an initial 500 mg intravenous phenytoin load, as used in the first half of his study, was inadequate. When we suggest using phenytoin at a 15 mg/kg dosage, the patient's weight is deduced from the most recent antenatal weight available. We do not actually weigh our patients before administration and did not intend to convey this impression. This approach has resulted in remarkably predictable blood levels.

As Prof. Dommisse points out, his results, although of concern, are not statistically significant. I appreciate the difficulty in convincing colleagues to try a new form of therapy instead of a well-established regimen, particularly when their initial experience with it is discouraging. I think it would be incorrect and premature to abandon the use of phenytoin in severe preeclampsia and eclampsia on the basis of preliminary results. There are several factors that individually or in combination may account for the imbalance noted.

I strongly support Prof. Dommisse's comment that a large randomized study is necessary. I suggest that such a study should consist of aggressive antihypertensive therapy throughout and include three protocols: magnesium sulfate, phenytoin, and no anticonvulsant, preferably with electroencephalographic monitoring in each group. It is hoped that such a study would put to rest the ongoing debate over which, if any, anticonvulsant should be used. Cape Town is one of the few units in the world where such a study would be feasible.

Digoxin-like immunoreactive factor and respiratory distress syndrome

To the Editors: Digoxin-like immunoreactive factor, as measured with a commercial digoxin antibody assay (Stratus I, Dade, Miami), begins to appear in measurable amounts (>1.9 ng/dl) in serum of normal pregnant women at approximately the thirty-fifth week of pregnancy.[1] Newborn respiratory distress syndrome also becomes infrequent at this gestational age. I found that when the maternal serum digoxin-like immunoreactive factor level is <1.9 ng/dl, the newborn will likely have respiratory distress syndrome.

As shown in Table I, 18 patients who had amniocentesis at 32 to 39 weeks for determination of fetal lung maturity (lecithin/spingomyelin) had simultaneous maternal serum digoxin (digoxin-like immunoreactive factor) determinations by our clinical laboratory. A positive relationship was found (χ^2, $p < 0.02$).

Eleven patients were delivered by cesarean section between 29 and 31 weeks' gestation because of severe hypertension; all had received steroids, anticonvulsants, and antihypertensive agents. Only four mothers had serum levels of digoxin >0.2 ng/dl immediately before delivery and none of their infants had more than mild respiratory distress syndrome as diagnosed by our neonatologists. By contrast, the other seven patients with no detectable maternal serum digoxin-like immunoreactive factor (digoxin) were all delivered of infants with severe respiratory distress syndrome.

These cases support the concept but do not prove a causal relationship between maternal levels of digoxin-like immunoreactive factor and fetal lung development. Both the elevated digoxin-like immunoreactive factor and minimal respiratory distress syndrome could reflect responses to fetal stress in preterm deliveries.[1] In pregnant sheep, Liggins and Forester[2] found that fetal adrenal cortisol production modulated both the onset of labor and fetal lung development. It has been proposed that digoxin-like immunoreactive factor is a steroid, has an adrenal origin, and plays the same role in humans as does cortisol in fetal sheep.[1]

Table I. Eighteen cases with serum endoxin and amniotic fluid lecithin/sphingomyelin determinations (receiving no drug therapy)

Maternal serum endoxin (digoxin) value	*Amniotic fluid lecithin/sphingomyelin ratio*	
	>1.8	*<1.9*
>0.19 mg/dl	7	2
<0.20 mg/dl	0	9

Digoxin-like immunoreactive factor is in part bound to serum proteins, serum levels are depressed by drugs (steroids, antihypertensives, and tocolytic agents) and there is a need for a more specific test of pregnancy-related digoxin-like immunoreactive factor.[1] Despite these problems, studies should continue of digoxin-like immunoreactive factor in pregnancy complications.

Dehydration-induced oligohydramnios

To the Editors: I read with interest the case report by Sherer et al. (Sherer DM, Cullen JBH, Thompson HO, Woods JR Jr. Transient oligohydramnios in a severely hypovolemic gravid woman at 35 weeks' gestation, with fluid reaccumulating immediately after intravenous maternal hydration. Am J Obstet Gynecol 1990; 162:770-1) in which severe nausea, vomiting, and diarrhea were associated with transient oligohydramnios. The authors attributed the oligohydramnios to maternal hypovolemia. However, the reactive nonstress test suggested that uterine blood flow was supplying adequate oxygenation to the fetal-placental unit.

I propose that maternal plasma hyperosmolality, rather than hypovolemia, resulted in the development of oligohydramnios. Although plasma osmolality was not measured at presentation, the plasma sodium level was elevated for pregnancy[1] and maternal urine sample demonstrated a potent antidiuretic response. Because

fetal plasma osmolality parallels maternal plasma osmolality (via transplacental flow), it is likely that a fetal antidiuretic response also was elicited. We have demonstrated that maternal dehydration (plasma osmolality increase of 10 mOsm) resulted in marked reductions in ovine amniotic fluid volume,[2] probably as a result of vasopressin-mediated reductions in fetal urine[3] and lung fluid production.[4]

These findings, together with the case report, illustrate the importance of maintaining adequate hydration during exercise, thermal exposure, or gastrointestinal losses in pregnancy.

Reply

To the Editors: We appreciate Dr. Ross' comments concerning our case report and the opportunity to reply. Unfortunately we did not test maternal plasma and urine osmolality; however, plasma sodium, which was high for pregnancy, and low maternal urine specific gravity suggest an antidiuretic response that was appropriate for the severe maternal hypovolemic condition. We agree that maternal hyperosmolality could possibly be the underlying mechanism resulting in oligohydramnios. However, it would be difficult to differentiate between the independent effects of maternal hypovolemia and maternal hyperosmolality (and possible subsequent fetal hyperosmolality) in this case. Fetal antidiuretic hormone secretion is indeed a possible response to maternal hyperosmolality and may explain the oligohydramnios via a decrease in fetal urine output as suggested above.

A reactive nonstress test, although reassuring, does not in itself imply uterine blood flow supplying adequate oxygenation to the fetal-placental unit.[1,2] A contraction stress test might have exposed a partially compromised fetal-placental unit as a result of compromised uterine blood flow.[3] Because of prematurity, oligohydramnios, and the possibility of causing iatrogenic umbilical cord compression, we elected not to perform this test. Retrospectively, because of the reaccumulation of the amniotic fluid volume with correction of the maternal hypovolemia, further testing for fetal well-being was not necessary.

A comment on thumbtacks for hemorrhage control

To the Editors: I read with interest the report by Patsner and Orr (Patsner B, Orr JW Jr. Intractable venous sacral hemorrhage: use of stainless steel thumbtacks to obtain hemostasis). Over the past 9½ years we have had occasion to use the thumbtack maneuver outlined in this article on two occasions. Both patients were undergoing extensive cytoreductive surgery. In both instances the venous bleeding could not be controlled by packing, clips, bone wax, or ligature. A steel thumbtack was used in each case and worked almost immediately. These are the only two instances in which we were in need of this "trick," so it is difficult to assess its efficacy.

Two caveats apply: First, not all thumbtacks are steel, and care must be taken not to use a metal that might corrode; second, when subsequent x-ray films are ordered for these patients, a panic-stricken call from the radiologist who is apt to be worried about the thumb-

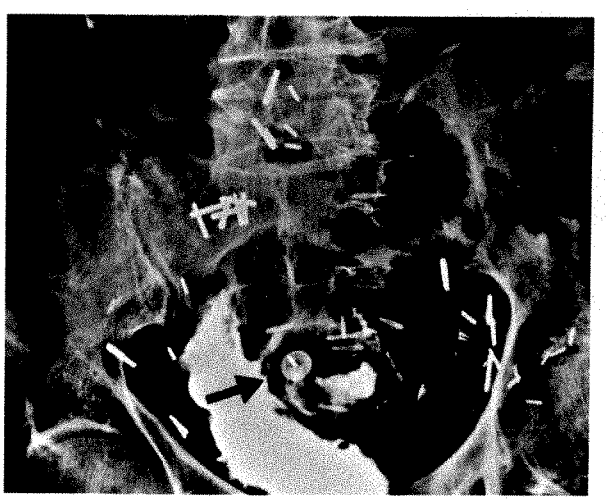

Fig. 1. Radiograph showing placement of thumbtack (PA).

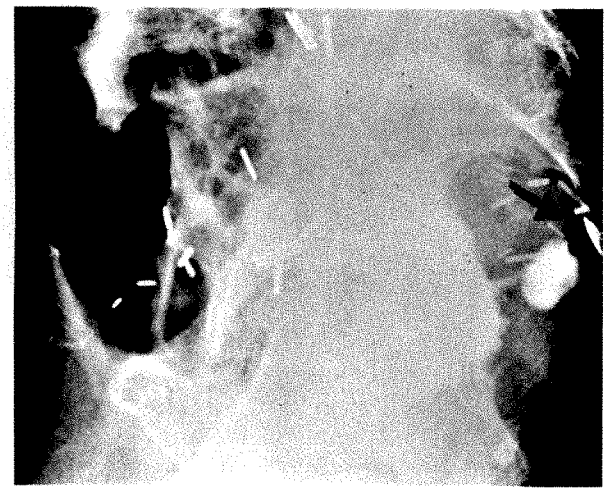

Fig. 2. Radiograph showing placement of thumbtack (lateral).

tack your patient ingested can be expected. Fortunately, as seen in the accompanying photographs, the lateral view clearly shows the placement of the tack in the sacrum.

I commend the authors for bringing more attention to this rarely needed but invaluable maneuver.

William J. Mann, MD

Department of Obstetrics and Gynecology, State University of New York at Stony Brook, Stony Brook, NY 11794-8091

Reply

To the Editors: Space limitations clearly prevented a comprehensive review of all the possible complications and requisite caveats that should accompany the use of stainless steel thumbtacks for control of presacral hemorrhage. Dr. Mann's points are both well taken: Only noncorrosive metals should be selected, and appropriate surgical history should be provided to radiologists as a matter of courtesy to avoid unnecessary confusion. (Of course, they might also be confused as to why anyone was still using wire to close incisions!)

Two additional points deserve mention. First, the risk for subsequent development of sacral osteomyelitis with this technique is unknown but must be kept in mind during patient follow-up. Second, although it would certainly be unusual to encounter (twice, no less) presacral venous plexus hemorrhage during cytoreductive surgery for ovarian cancer, Dr. Mann's two cases clearly illustrate that the technique may be required in situations other than elective presacral neurectomy.

Early pregnancy failure—appropriate terminology

To the Editors: I was excited to see the title of the Clinical Opinion by Pridjianand and Moawad (Pridjian G, Moawad A. Missed abortion: still appropriate terminology? Am J Obstet Gynecol 1989;161:261-2). However, after carefully reading the article it appears that even the new terms they recommend are already outdated.

I concur that advances in ultrasonography have changed our concepts about early pregnancy failure. Until recently, the accepted ultrasonographic definition for "missed abortion" was a crown-rump length of 15 mm without evidence of cardiac activity.[1] A "blighted ovum" or anembryonic pregnancy was a gestational sac ≥25 mm mean sac diameter without an embryo.[2] The introduction of the vaginal probe has allowed a high degree of resolution in spite of magnification. This results in a form of "sonomicroscopy" wherein structures that cannot be seen with the naked eye can be imaged. Investigators have reported seeing a cardiac signal with M-mode technology before being able to image the actual embryo.[3] This should not be surprising since the embryonic disc, amnion, and yolk sac are present even in the early gestational sac. They are simply too small to be imaged even with the sonomicroscopy capability currently available. Therefore the classic distinction between blighted ovum and missed abortion becomes blurred. Most anembryonic pregnancies are not truly without embryos. They simply lose viability before our ability to image them. Furthermore, in many cases there is initial early embryonic development with subsequent loss of viability and then embryonic resorption.[4] This then ultimately results in the sonographic appearance of an "empty sac."

I agree with the authors that there may be different causes for intrauterine pregnancy failure. Certainly, the earlier it occurs, the more likely it is related to chromosomal polyploidy, whereas in later failures abnormalities of implantation, placentation, associated fibroids, or infection may be causative. I applaud the authors' attempt to update terminology but I would suggest that they go even further as outlined above.

Conservative management of cervical pregnancy with subsequent fertility

To the Editors: I read the article by Bachus et al. in the February, 1990, issue with great interest (Bachus KE,

Stone D, Suh B, Thickman D. Conservative management of cervical pregnancy with subsequent fertility. AM J OBSTET GYNECOL 1990;162:450-1). However, I question the wisdom of performing suction curettage in the patient mentioned in the article.

As reported, this procedure resulted in violent hemorrhage. Fortunately, in this patient the profuse hemorrhage that resulted in reduction of hematocrit from 38% to 28%, despite administration of packed red blood cells, was controlled by the means described by the authors. Not every patient with this problem is a candidate for suction curettage because this procedure may result in not only violent hemorrhage as described by the authors, but also life-threatening hemorrhage with inherent severe medical and legal complications. I respectfully disagree with the statement that "this approach should be considered a standard of care in those patients desiring future fertility." This may imply that the clinician may perform suction curettage in all such patients, which frankly may result in severe and life-threatening hemorrhage.

I would like to propose that medical rather than surgical management of these patients may be lifesaving in this condition. The administration of methotrexate into the gestational sac or systemic use of methotrexate, which is successfully used in tubal and cervical pregnancy, is an excellent medical approach. Methotrexate, 1 mg/kg, alternating on a daily basis with folinic acid, 0.1 mg/kg (total of four doses) has been suggested. In their report Oyer et al.[1] used only two doses of the above regimen and successfully treated cervical pregnancy without the occurrence of severe hemorrhage. These drugs should be used only if serum transaminase and other laboratory test results are normal.

In summary, individualization of patients with cervical pregnancy who wish future fertility is in order, and a decision should be made whether a surgical approach or medical treatment is indicated, as outlined above, for the best management for such patients.

Jahangir Ayromlooi, MD

Department of Obstetrics and Gynecology, UMDNJ-Robert Wood Johnson Medical School, St. Peter's Medical Center, 254 Easton Ave., New Brunswick, NJ 08903

Reply

To the Editors: We thank Dr. Ayromlooi for his interest in and comments concerning our article. This allows further discussion about treatment options for this interesting, yet sometimes terrifying condition.

When we stated that this approach be considered a standard of care in those patients desiring future fertility, we were referring to conservative means of management as opposed to hysterectomy. The purpose of this article was not necessarily to advocate surgical means of treatment compared with methotrexate therapy, but in light of Dr. Ayromlooi's comments that "medical rather than surgical management of these patients may be lifesaving," we think that a more complete description of the benefits, risks, and outcomes of these two methods is necessary.

It is apparent from the cases in the literature, that most cases of cervical pregnancy are not diagnosed preoperatively.[1, 2] Clinicians perform curettage for what is thought to be an incomplete or inevitable abortion only to encounter the hemorrhage associated with this rare form of ectopic pregnancy. Obviously, in this situation mechanical packing or surgical therapy are the only methods available, and familiarity with the method described can avoid significant morbidity. A large Foley balloon, with or without adjunctive cerclage, can be applied expeditiously to control hemorrhage. Its effectiveness has been reported[3, 4] and avoids the need for more extensive surgery such as internal iliac artery ligation or hysterectomy.

The "wisdom of performing suction curettage" in this patient because of the inherent hemorrhage potential is questioned by Dr. Ayromlooi. The concern is that if performed in all patients with cervical pregnancy, life-threatening hemorrhage may result. Admittedly, curettage of this form of ectopic pregnancy does carry a risk of significant hemorrhage because of the poor contractile properties around the implantation site within the cervix and transfusion of up to 6 units has been reported.[5] Despite the blood loss, none of the patients reported who were treated by the techniques described in our report have required more definitive therapy. It is hoped that increased early detection of cervical pregnancy by clinical and ultrasonographic methods will result in preoperative preparation that will reduce the need for transfusion.

This hemorrhage, however, is not unique to surgical management as Dr. Ayromlooi implies. Medical management with methotrexate also has similar bleeding potential. Of the 10 patients with cervical pregnancy treated with methotrexate reported in the literature, two had reports of large hemorrhages that ultimately led to hysterectomy.[2] Furthermore, these bleeding episodes occurred up to 18 days after methotrexate therapy.[2, 6] This is disconcerting because the patient at this point may already be home. One additional patient required hysterectomy for persistence of the cervical mass after this medical therapy,[7] and one patient had hemorrhage that ultimately was controlled with adjunctive use of internal iliac ligation and intracervical balloon tamponade.[8]

This medication also carries a risk of toxicity that cannot be ignored. Stomatitis and elevated serum transaminase levels limited therapy in two of the reported 10 cases.[7, 9] In fact, the patient in the case cited by Dr. Ayromlooi had methotrexate use discontinued after two of the four planned doses because of hepatic toxicity.[9]

We agree that not all patients with cervical preg-

nancy are candidates for conservative treatment modalities. Some authors have recommended limiting attempts to conserve the uterus to the first 8 weeks of pregnancy.[10, 11] This may be particularly true for those patients treated with methotrexate, because one of five patients treated within the first 8 weeks required additional therapy to control hemorrhage.[2] Beyond 8 weeks, two of three cases required surgical intervention for control of bleeding.[7, 8] Although the numbers are still small, this trend is similar to the experience with methotrexate in treating tubal ectopic pregnancies in which excessive size and high human chorionic gonadotropin titers have been shown to have poorer outcomes.[12, 13] Currently, experience with contemporary conservative treatment methods beyond the first trimester is extremely limited.

Choice of the optimal treatment for a patient who wishes to preserve fertility is difficult. It should be recognized that both of these treatment modalities have inherent morbidities that must be considered by the patient and the physician when selecting a conservative treatment plan.

Can shoulder dystocia be prevented?

To the Editors: Although the recent article by O'Leary and Leonetti (O'Leary JA, Leonetti HB. Shoulder dystocia: prevention and treatment. AM J OBSTET GYNECOL 1990;162:5-9) was published in the Clinical Opinion section, I am concerned that some of the statements might be misconstrued. The third sentence in the paper implies that many shoulder dystocias can be prevented by quoting a source that states that many shoulder dystocias can be anticipated. Any algorithm to predict shoulder dystocia should include an estimation of the number of falsely alarming predictions of damage to the infant. In other words, how many "unnecessary" cesarean deliveries are necessary to prevent each case of shoulder dystocia?

The suggestion that "once a shoulder dystocia, always a cesarean" obviously ignores the fact that there are complicated dynamics that predict whether shoulder dystocia will occur. Just as the necessity for a prior cesarean delivery for management of cephalopelvic disproportion poorly predicts the need for subsequent cesarean delivery for the same indication, in the absence of more compelling data we should not accept the thought that shoulder dystocia will predictably repeat itself.

Finally, the order of suggested treatment of shoulder dystocia that the authors propose in Table IV is certainly debatable; however, I would suggest that the maneuvers begin with the least invasive, that is, the McRoberts maneuver. Proceeding with a list as suggested is sensible, although I still am concerned about the suggestion that the head can be forcibly replaced with safety. Although this may be an appropriate procedure in the authors' hands, multisite performance in more patients will make me (and many others) feel more comfortable.

Whereas it is certainly true that increasing the cesarean section rate will, as the authors propose, reduce the incidence of shoulder dystocia, it will also increase the incidence of maternal morbidity and mortality. I hope that we can balance these risks in adopting a safe and sane standard for the management of this uncommon, but frightening and potentially disastrous complication of pregnancy.

David A. Nagey, MD, PhD

Section of Obstetrics, Division of Maternal-Fetal Medicine, School of Medicine, University of Maryland at Baltimore, 22 South Greene St., Baltimore, MD 21201

Reply

To the Editors: We appreciate Dr. Nagey's thoughtful and meaningful remarks. It is hoped that by raising the level of anticipation of shoulder dystocia a more thorough clinical assessment would allow the physician to accumulate more data and thus recognize more risk factors for shoulder dystocia (i.e., the flat pelvis).

The expression "once a shoulder dystocia, always a cesarean" is based on the assumption that the same set

of clinical parameters is operative at the time of the next delivery (e.g., macrosomia, glucose intolerance).

To date, 34 cases of cephalic replacement have been collected from around this country with only one failure and one major maternal complication. We agree that the McRoberts maneuver is most effective.

Measurement of cardiac output with impedance cardiography

To the Editors: An interesting article was published in the September 1989 issue of the JOURNAL (Masaki DI, Greenspoon JS, Ouzounian JG. Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution. AM J OBSTET GYNECOL 1989;161:680-4) concerning the measurement of cardiac output in patients with cardiac problems, pancreatitis, septic shock, and pregnancy-induced hypertension. More than 10 years ago, in 1978, we investigated cardiac output and stroke volume index in pregnant women with threatening premature birth compared with normal pregnancies in the standing, supine, and left lateral positions using a Minnesota impedance cardiograph. We found a statistically highly ($p < 0.005$) significant reduction of cardiac output in the standing position in patients with premature labor that disappeared in the lying positions and a significant ($p < 0.025$) reduction in stroke volume, which disappeared in the supine position but persisted in the left lateral position.

The absolute values of cardiac output were in the same range as in the investigations by Masaki et al.

Labor epidural analgesia and dystocia-related cesarean section

To the Editors: Does labor epidural analgesia increase the need for obstetric intervention? Most published studies addressing this question, some that implicate and others that exonerate labor epidural analgesia, have design flaws. The same is true of two recent reports claiming that labor epidural analgesia increases the rate of dystocia-related cesarean section.[1, 2] In the first, parturients chose their methods of pain relief and altered it at will.[1] In the second report involving "matched" subjects, the anesthesiologist and obstetrician prescribed analgesia.[2] Furthermore, their patients were not matched for height and weight, factors that are likely to influence pelvic bony and soft tissue anatomy.[3]

Thorp et al.[1] argue that a controlled, randomized comparison between labor epidural analgesia and parenteral narcotics would be unethical and liable to patient dropout.[1] However, Philipsen and Jensen[4] have prospectively compared labor epidural analgesia and intramuscular meperidine in a randomized study and found no differences in obstetric interference rates. Cesarean section was performed for management of cephalopelvic disproportion in nine of 10 and three of six parturients, and malrotation was present in three of nine and none of a group of three patients, respectively. Their cesarean section rates (labor epidural analgesia, 7.8% or 4/51 and meperidine, 5.9% or 3/51) are thus commensurate with those of others.[1]

Thorp et al.[1] gave patients a bolus dose of 0.25% bupivacaine and infused 0.125%. Diro and Beydoun[2] and Philipsen and Jensen[4] used intermittent injections of 0.25% and 0.375% bupivacaine, respectively. Lamont et al.[5] compared bupivacaine infusion with intermittent "top-ups" but "allowed a passive phase of second stage of up to 3 hours in each group." Newer labor epidural analgesia techniques that offer optimal maternal analgesia without muscle weakness, and loss of perineal pressure sensation[6-8] may thus favor spontaneous vaginal delivery.

Thorp et al.[1] stress the current medicolegally inspired reluctance of some obstetricians to use forceps. Are their results perhaps related more to obstetric preference rather than labor epidural analgesia? Diro and Beydoun[2] delivered nine patients who had received epidural anesthesia with forceps, within 2 hours of reaching 10 cm dilatation. Prolonging the second stage up to 3 hours might have changed the clinical situations.[5]

Forty percent of nulliparous women suffer severe pain with childbirth.[9] This may jeopardize the fetus.[10, 11] Labor epidural analgesia provides maternal analgesia with improved transplacental exchange.[12, 13] A large, controlled, prospective multicenter study incorporating newer labor epidural analgesia and labor management techniques[6-8] could resolve the issue.[14, 15] Patients could be randomized to receive either labor epidural analgesia with intravenous saline solution or intravenous meperidine with epidural saline solution, allowing escape to labor epidural analgesia for unbearable pain. When the grave accusations being leveled at labor epidural analgesia are considered,[1, 2] this approach would be ethical in our view.

Pemphigus in pregnancy

To the Editors: We read with interest the report by Kanwar et al. of another case of pemphigus vulgaris in pregnancy (Kanwar AJ, Kaur S, Abraham A, Nanda A. Pemphigus in pregnancy. AM J OBSTET GYNECOL 1989;161:995-6). We heartily support the authors' conclusion that "it is important that physicians and obstetricians be aware of the problem" and "consider as problematic the treatment of pemphigus during pregnancy." Pemphigus vulgaris during pregnancy that affects the fetus is very rare. The authors erroneously mentioned 48 such cases[1]; however, this figure also includes cases of pemphigus foliaceus, which does not affect the neonate and thus does not pose a difficult therapeutic problem during pregnancy.

We did express our opinion[2] that pemphigus vulgaris may severely endanger the fetus because the stillbirth rate for the reported infants born to mothers with this immune-mediated disease during pregnancy is 23%. This is probably a result of the effect of treatment. It may be the result of high doses of corticosteroid therapy, masking a possibly overwhelming infection or causing placental insufficiency. We might find support for this in the report by Kanwar et al. of a newborn with a birth weight of 1800 gm at 36 weeks' gestation, who was obviously small for gestational age, possibly because of placental insufficiency, after the mother had been treated with 60 mg prednisolone per day for some time.

We recommend repeated plasmapheresis as an alternative treatment to improve the precarious state of a patient or fetus with pemphigus vulgaris, thus avoiding high doses of corticosteroids when a high titer of circulating pemphigus antibodies is present.[3] Plasmapheresis should contribute to the alleviation of risk to the infants of pregnant women with pemphigus vulgaris.

3. Metzker A, Merlob P. Pemphigus in pregnancy: a reevaluation of fetal risk. AM J OBSTET GYNECOL 1987;157: 1012-3.

Reply

To the Editors: We thank Drs. Metzker and Merlob for their comments on our article. Although we did mention that only 48 patients in whom pemphigus developed or who had recurrent pemphigus during pregnancy have been reported in the literature, it was not specified that all these cases were of pemphigus vulgaris. Because transplacental transfer of IgG antibodies does occur in pemphigus, why pemphigus foliaceus does not affect the newborn is a matter of conjecture. The milder form of the disease, low levels of circulating antibodies, and smaller doses of corticosteroids required for control of the disease perhaps protect the fetus.

We do not agree with their suggestion that repeated plasmapheresis is an alternative treatment to improve the precarious state of a patient or fetus with pemphigus vulgaris. At best plasmapheresis is still an experimental procedure in treatment of pemphigus and its use is presently restricted to severe corticosteroid-resistant cases of pemphigus.[1,2] In our opinion it is not worthwhile to subject the mother and fetus to the extensive stress of this repeated procedure with the risks and ill effects of its own.

Graphic mnemonic for variable decelerations

To the Editors: Our hospital uses the system of Kubli et al. (Kubli FW, Hon EH, Khazin AF, Takemura H. Observations on heart rate and pH in the human fetus during labor. AM J OBSTET GYNECOL 1969;104:1190-206) to classify the severity of variable fetal heart rate decelerations. However, the definitions can be cumbersome to memorize and recall. I have found the following graphic mnemonic very helpful in teaching on rounds.

Picture a graph divided into nine zones by four lines, as in Fig. 1. The horizontal axis represents the duration of the deceleration. The vertical axis represents the lowest level to which the heart rate drops.

Locate the point that characterizes the deceleration in question. If the point falls within the lower right-hand zone, the deceleration is severe. If the point falls within the two zones adjacent to the severe zone, the deceleration is moderate.

Thus it is only necessary to remember the zone locations and the values determining the four lines.

Stability of human chorionic gonadotropin and its α-subunit

To the Editors: We were pleased to read that Petrocik et al. (Petrocik E, Wassman ER, Kelly JC. Prenatal screening for Down syndrome with maternal serum human chorionic gonadotropin levels. AM J OBSTET GYNECOL 1989;161:1168-73) confirmed our findings[1]

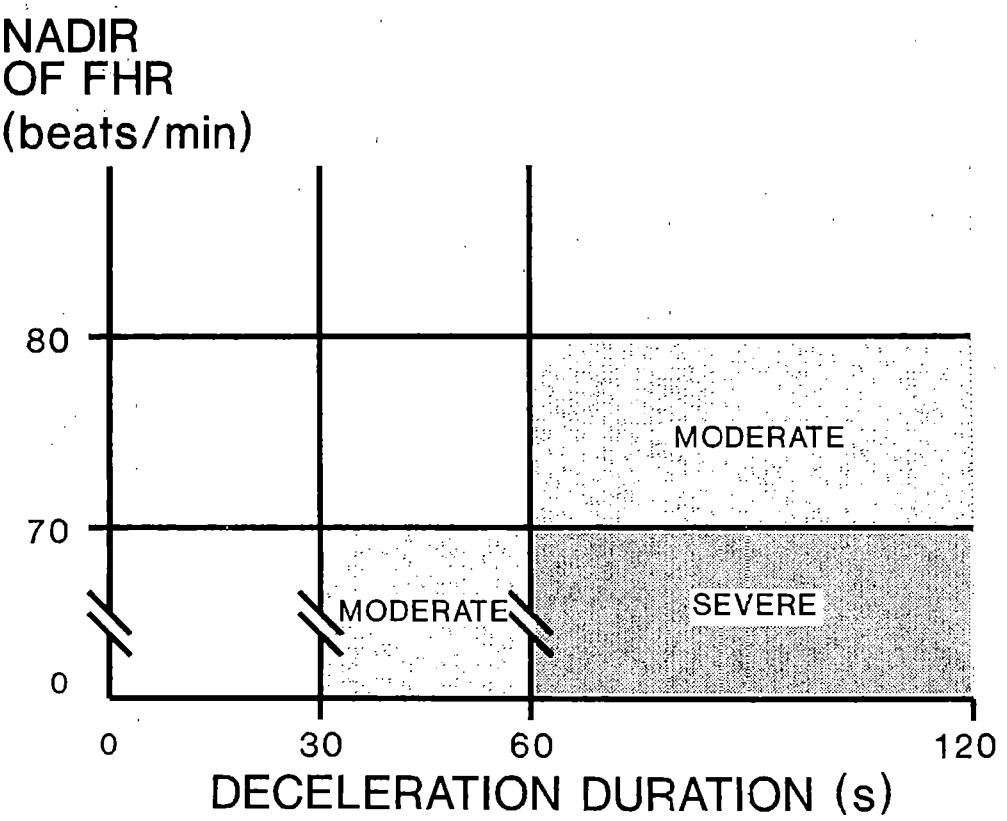

Fig. 1. Graphic mnemonic for identifying the severity of variable decelerations.

on the remarkable stability of the α-subunit of human chorionic gonadotropin in unfrozen whole blood and unfrozen and frozen serum and plasma samples. However, the authors regrettably implied (in the third sentence, second paragraph, second column on page 1172) that we had not studied the stability of the whole human chorionic gonadotropin molecule and that their study now investigates this deficiency. We would like to point out that our published article does in fact also contain data on the stability of the whole human chorionic gonadotropin molecule. We are pleased that Petrocik et al. also confirmed this aspect of our published study.

Vaginal probe ultrasonography and ectopic pregnancy

To the Editors: It was with great interest that I read the article by Stiller et al. (Stiller RJ, deRegt RH, Blair E. Transvaginal ultrasonography and patients at risk for ectopic pregnancy. AM J OBSTET GYNECOL 1989;161: 930-3). I agree with their conclusions about the advantages of the vaginal probe and its combination with the determination of a quantitative human chorionic gonadotropin level will allow the majority of patients to be offered a definitive diagnosis at initial evaluation or within 48 hours. However, I would like to make two additional points that I think would further enhance the clinical usefulness of their technique.

First, the use of curettage in examination of unstained material with low-power magnification will be an appropriate next step in triage for certain patients.[1] This will pertain when the human chorionic gonadotropin levels rise at a subnormal rate of rise or when the human chorionic gonadotropin level exceeds a definitive discriminatory zone as established by one's own laboratory. Such cases may represent failing intrauterine pregnancies or possibly ectopic pregnancy, and performance of curettage and examination of tissue to distinguish villus material from maternal decidua can be a valuable next step in the triage of such patients. Such a procedure would have prevented the unnecessary laparoscopy performed in their cited case in which misdiagnosis of an intrauterine gestation occurred.

Second, it is unfortunate that some authors have chosen to use the "double decidual sac" sign[2] as the ultrasonographic proof of an intrauterine pregnancy. There is ample evidence that the echogenic "rind" around the sonolucent center that is visualized is not the result of two layers of decidua being fused; rather, the primary trophoblastic villi, as they come off the chorionic membrane, invade maternal decidua and produce a trophoblastic decidual reaction that is highly echogenic. The chorionic cavity is fluid filled, contains the embryonic complex, and is sonolucent. Initially the primary villi are very homogeneous (they have not yet begun to branch and proliferate), and as they invade maternal decidua they produce the classic echogenic "rind" around the sonolucent chorionic cavity to which the authors refer. Outside the uterus (ectopic pregnancy), the echogenicity is a result of primary villi invading decidualized tubal endothelium. Unfortunately, the authors, who have obviously done high-quality ultrasonography with modern vaginal ultrasonographic equipment, have chosen an 8-year-old article in which research was done transabdominally to describe the anatomic landmarks that they chose to follow.

Reply

To the Editors: I appreciate the comments on our article. I agree that there may be some circumstances in which examination of uterine contents for the presence of chorionic villi may be useful in the differentiation of the failing intrauterine pregnancy from the ectopic pregnancy. Admittedly, this would have been useful in one case in our original series; however, in more than 50 patients with ectopic pregnancies seen subsequently, we have not needed to perform curettage for evaluation of chorionic tissue to confirm pregnancy location appropriately.

With regard to the criticism of the term "double decidual sac sign" used in our article, it must be noted that the description of an anechoic area surrounded by an echogenic rind has been widely accepted in the ultrasound literature as definitive evidence of a gestational sac, and it is for this purpose that the term was used. I would also assume that it was for similar reasons that Dr. Goldstein used this same term in his article

published only 2 months before the submission of our article.[1]

A convenient method to identify prior surgical procedures

To the Editors: Current standards of practice mandate adequate documentation of medical care. Such standards derive in part from legal concerns but increasingly, obstetric and gynecologic care is often predicated on an adequate disclosure of a patient's prior medical and surgical history. As examples, repeat cesarean sections may be avoided and a trial of vaginal delivery attempted if documentation of a lower uterine segment incision can be made.[1] Similarly, tubal reanastomoses may be scheduled based solely on a review of the operative report describing the type of tubal ligation, thereby avoiding the cost and risk of laparoscopy.[2] However, the mobility of our population, particularly evident in the military services, frequently results in a fragmented medical record, and the question remains with regard to exactly what sort of care had previously been rendered.

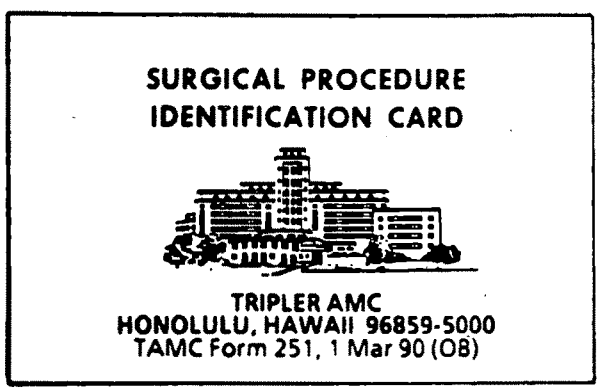

Fig. 1. Identification card for surgical procedures.

The concept of personally carried medical records is one potential solution and in fact is not new to obstetrics and gynecology. A cumulative, hand-carried obstetric record *(mutterpass)* is common practice in the Federal Republic of Germany, and a pocket identification card has been used in the gynecologic population to document the placement of an intrauterine contraceptive device. We extended this concept to surgical procedures and designed an identification card to document the type of either cesarean section or tubal surgery (Fig. 1). The card provides space for identification of the type and date of the procedure and is similar in size to a standard credit card. On the reverse side, we chose to display a sketch of our medical center and our address, although any logo(s) or private practice name(s) could be depicted. We currently distribute the card to any patient who has either delivery by cesarean section, tubal ligation, or tubal surgery when the risk of ectopic pregnancy is increased. Use of this card should provide a convenient and immediate means to document prior surgical care, especially in emergent circumstances, and may be used while awaiting formal medical records and operative reports.

Fetal Doppler velocimetry in twins

To the Editors: Divon et al. (Divon MY, Girz BA, Sklar A, Guidetti DA, Langer O. Discordant twins—A prospective study of the diagnostic value of real-time ultrasonography combined with umbilical artery velocimetry. AM J OBSTET GYNECOL 1989;161:757-60) performed umbilical artery velocimetry with a continuous-wave Doppler system and stated that the presence of either a 15% difference in ultrasonographic estimates of fetal weight or a 15% difference in systolic/diastolic ratios correctly identified 78% of discordant pairs. With a pulse-wave Doppler-duplex system enabling accurate sampling of vessel because of its depth resolution, we have shown[1] that from ultrasound criteria and Doppler study of the umbilical and fetal internal carotid arteries, decreased fetal internal carotid artery pulsatility index (cutoff value ≤ 1.2) was found to be the best predictor of twin discordancy (sensitivity 83%, specificity 95%, positive predictive value 91%, negative predictive value 91%). Pulsatility index determination provides direct

evidence of the brain-sparing effect in the growth-retarded fetus.[2, 3]

The umbilical artery Doppler assessment may present problems in twin gestations because it is not always easy to verify which fetus is associated with the umbilical vessel under study.

Our findings suggest that it may be more practical to use ultrasonographic weight estimation below the 10th percentile (sensitivity 67%) or below the 25th percentile (sensitivity 92%) as a screening tool and then perform Doppler studies to determine the twin fetus at risk. With these sequential tests the specificity is improved (91%, 98%) at the expense of reduced sensitivity (56%, 76%, respectively).

Reply

To the Editors: We appreciate the interest of Dr. Degani in our recent article. As suggested, umbilical artery velocimetry studies are occasionally difficult in twin gestation. Pulsed-wave, duplexed devices may provide some help; however, we do not think that these devices can establish with certainty the association between the umbilical cord and the fetus.

Our experience with discordant twins indicates that a combined analysis of both Doppler velocimetry and estimated fetal weight yields superior results to these obtained by initial analysis of the differences between fetal weights. Therefore we see no need for a "two-step" diagnostic approach.

Ketoconazole treatment of Cushing's syndrome in pregnancy

To the Editors: I was most interested to read the useful and comprehensive review of Cushing's syndrome and pregnancy by Aron et al. (Aron DC, Schnall AM, Scheeler LR. Cushing's syndrome and pregnancy. Am J Obstet Gynecol 1990;162:244-52).

Experience with medical therapy has been extremely limited. Ketoconazole blocks 11β-hydroxylase, 17α-hydroxylase, and cholesterol side-chain cleavage in adrenal steroidogenesis and has been useful in the control of hypercortisolism, although it is teratogenic and embryotoxic in animals.

Amado et al.[1] recently reported the use of ketoconazole in a woman with deteriorating Cushing's syndrome caused by an adrenal adenoma from 32 weeks' gestation until 36 hours before cesarean section at 37 weeks. The clinical and biochemical response was excellent. Cortisol and aldosterone levels decreased, the level of 11-deoxycortisol increased, and there was no diminution in the levels of either estradiol or progesterone; a normal healthy female infant was delivered and remained well after 18 months.

Obviously, "one swallow doesn't make a summer," but their work deserves further investigation.

Vaginal birth after abdominal delivery

To the Editors: We would like to comment on the article by Yetman and Nolan (Yetman TJ, Nolan TE. Vaginal birth after cesarean section: A reappraisal of risk. Am J Obstet Gynecol 1989;161:1119-23). The authors conclude that successful vaginal birth after cesarean section carries a higher risk for significant perineal lacerations. This conclusion cannot be drawn from the data presented because the authors do not report the number of episiotomies used for delivery within the study and control groups. Because midline episiotomy predisposes the anal sphincter and rectum to injury,[1-4] a higher incidence of episiotomy in either group could have confounded the results.

The combination of vaginal vault lacerations, cervical lacerations, and third- and fourth-degree lacerations under the single heading of perineal lacerations is also misleading. These four separate categories of birth canal trauma should have been analyzed separately. Whether the incidence of any of these individual lacerations would have been different between the control and study groups by a statistically significant margin cannot be ascertained from the data as published. This is important because the authors draw attention to rectovaginal fistula as a potentially serious consequence of "perineal lacerations." However, rectovaginal fistulas are the occasional consequence of fourth-degree perineal lacerations but not of cervical, vaginal vault, or third-degree lacerations. Similarly, it would be important to know if cervical lacerations were significantly more common in the study group, because cervical lac-

erations may predispose patients to incompetent cervix in future pregnancies. In short, combining the several types of perineal lacerations may have contributed to the data achieving statistical significance, but it confuses the really important clinical issues.

Corticotropin-releasing hormone in amniotic fluid

To the Editors: I read with great interest the article by Sasaki et al. (Sasaki A, Shinkawa O, Yoshinaga K. Immunoreactive corticotropin-releasing hormone in amniotic fluid. AM J OBSTET GYNECOL 1990;162:194-8). The authors stated that their article is the first report on the presence of corticotropin-releasing hormone in amniotic fluid, but we remind readers that in 1988 we published an article on corticotropin-releasing hormone in human amniotic fluid in the JOURNAL.[1] We found a concomitant increase of corticotropin-releasing hormone and cortisol levels in amniotic fluid with advancing gestation and increased concentrations of corticotropin-releasing hormone in pregnancies complicated with preeclampsia and fetal intrauterine growth retardation. We speculated that increased intrauterine release of corticotropin-releasing hormone in preeclampsia may be of placental origin and may stimulate fetal pituitary-adrenal axis and promote the process of fetal maturation in obstetric stress. In addition to the placenta, the amnion may be a potential source of corticotropin-releasing hormone in amniotic fluid because we have found an intensive immunostaining of corticotropin-releasing hormone in this tissue.[2]

2. Saijonmaa O, Laatikainen T, Wahlström T. Corticotropin-releasing factor in human placenta: localization, concentration, and release in vitro. Placenta 1988;9:373-85.

Reply

To the Editors: We have carefully considered the criticisms raised by Dr. Laatikainen and appreciate the opportunity to clarify some aspects of our study.

We believe it is important to characterize the total immunoreactive materials precisely by gel filtration or high-pressure liquid chromatography, if the presence of corticotropin-releasing hormone in amniotic fluid is to be proved. The presence of total immunoreactivity does not indicate the presence of biologic or intact corticotropin-releasing hormone molecule. Indeed, we found 60% of total corticotropin-releasing hormone—like immunoreactivity in amniotic fluid was authentic corticotropin-releasing hormone molecule and the remaining 40% was smaller fragment. In this regard our article was the first report on the presence of authentic corticotropin-releasing hormone in human amniotic fluid. The physiologic significance of corticotropin-releasing hormone in amniotic fluid is not yet known. We doubt Dr. Laatikainen's speculation that corticotropin-releasing hormone in amniotic fluid may stimulate the fetal pituitary-adrenal axis and promote fetal maturation. Corticotropin-releasing hormone levels in amniotic fluid are not high enough to promote its biologic activity, and it is also unclear what type of route is present from amniotic fluid to fetal pituitary gland. We previously purified placental corticotropin-releasing hormone and its partial structure was identical to rat corticotropin-releasing hormone.[1] Maternal plasma corticotropin-releasing hormone levels during late pregnancy are extremely high,[2] and the fetal plasma corticotropin-releasing hormone level is 100 times less than that of the maternal level. Corticotropin-releasing hormone present in maternal peripheral plasma is biologically active and its level is two times higher than that of hypothalamic-portal plasma in rats. Therefore, we conclude that placental corticotropin-releasing hormone is primarily secreted into maternal plasma and has a role in stimulation of the maternal pituitary-adrenal axis during pregnancy.[3] Currently there is no direct evidence whether it may have a function to the fetal side. Finally, the precise origin of corticotropin-releasing hormone in amniotic fluid is not clear; we have already discussed several possibilities regarding its origin. The amnion may be the origin if corticotropin-releasing hormone is present as indicated by immunostaining. However, we also emphasize that immunostaining studies sometimes produce pitfall results.[4]

Ultrasonographic dating of very early pregnancy

To the Editors: How does one date a normal singleton intrauterine pregnancy ultrasonographically before detection of the crown-rump length[1] or early fetal cardiac activity[2]?

We attempted to answer this question in 1984 by relating the mean gestational age to mean sac diameter.[3] Since then we have used the following simple formula[4] for dating several hundred early normal singleton intrauterine pregnancies and have found it to be reliable and useful with mean sac diameters ≤15 mm by either transabdominal[2, 3] or transvaginal techniques: Mean gestational age in days = 30 + Mean sac diameter in millimeters (i.e., 5 mm sac = 35 days). The 95% confidence limits are ±3 days, assuming the pregnancy is normal.

The mean gestational age is menstrual age (conceptional age + 2 weeks). The mean sac diameter is obtained by averaging the length, width, and depth on perpendicular ultrasonograms through the largest portion of the gestational sac. All measurements should be from sac-fluid to fluid-sac interfaces.[2, 3]

Maternal exercise and early pregnancy outcome

To the Editor: We enjoyed the article by Dr. Clapp on maternal exercise and early pregnancy outcome (Clapp JF. The effects of maternal exercise on early pregnancy outcome. Am J Obstet Gynecol 1989;161:1453-7). It adds to the growing body of literature that supports the position that judicious antigravitational exercise before and during pregnancy does not adversely affect outcome.

We agree that the power of his experimental design would increase with wider representation of the populace. Cross-cultural parameters may also be considered variables. Furthermore, a cross-sectional/longitudinal approach based on percentages of body fat versus level of exercise over a 24-month period would provide data on changes of body fat and levels of exercise before and during pregnancy versus outcome. In this way control over possible experimental bias would be increased.

Because the reliability of uncollaborated self-reporting has been shown to be low, efforts should be made to collaborate all reports of duration and intensity of exercise per day.

Further strength of design can be accomplished by controlling variances in diet. Records of quality and quantity of calories consumed during every 24-hour period would provide another axis of data by which possible dietary influences on pregnancy outcome may be made apparent.

Another possible effect may lie in unaccounted for physiologic changes that can occur when a usually active woman ceases all forms of exercise when she becomes pregnant. Thus a comparison between exercise before and during pregnancy, exercise before but not during pregnancy, and pregnancy outcome would be useful.

As Americans become more health conscious, the question of the effects of exercise, one's overall health, and pregnancy outcome will become increasingly important. Continuation of the author's research in this area is certainly warranted and welcomed.

Normal amniotic pressure in oligohydramnios after preterm rupture of membranes

To the Editors: In their article on amniotic pressure in oligohydramnios (Nicolini U, Fisk NM, Rodeck CH, Talbert DG, Wigglesworth JS. Low amniotic pressure in oligohydramnios—Is this the cause of pulmonary hypoplasia? Am J Obstet Gynecol 1989;161:1098-101), Nicolini et al. propose low amniotic pressure as a possible mechanism contributing to lung hypoplasia in pregnancies complicated by reduced liquor volume. They also state that they have not measured the intraamniotic pressure in cases of oligohydramnios as a result of premature rupture of the membranes.

We have performed pressure measurements in three pregnancies complicated by early rupture of membranes and resultant oligohydramnios with a fluid-filled system and a solid-state pressure transducer. Intraamniotic pressures are zeroed to the top of the maternal abdomen.

The intraamniotic pressures were recorded before and after the infusion of 200 ml of Hartmann's solution into the amniotic cavity to facilitate ultrasonographic visualization of the fetus. In the first case in which liquor was draining for 2 weeks before the procedure at 20 weeks, the intraamniotic pressure was 12 mm Hg. Preterm labor occurred at 29 weeks and a male infant weighing 1425 gm was delivered. He died of respira-

tory failure at 43 days after a stormy neonatal course; autopsy was refused. The other two cases involved preterm rupture of membranes at 21 and 22 weeks, respectively. In the former, intraamniotic pressure was 3 mm Hg. The baby was delivered at 36 weeks and 3 days, and had an uncomplicated postnatal period. The pressures in the last case were 9 mm Hg before and 10 mm Hg after infusion, and this pregnancy resulted in preterm labor at 31 weeks' gestation. The infant died in the neonatal period and autopsy confirmed pulmonary hypoxemia.

According to published data,[1,2] the intramniotic pressures in these cases were within the normal range. Nicolini et al. suggest that the low pressure in oligohydramnios contributes to pulmonary hypoplasia by allowing intrapulmonary fluid to escape from the lungs down a pressure gradient. In these cases with normal intraamniotic pressure, this is unlikely to be a mechanism, particularly in the first case in which the pressure was at the upper limit of normal. Possibly the higher intraamniotic pressure is a factor in the genesis of preterm ruptured membranes. The first infant died of chronic lung disease. This could have been caused by prematurity alone, but the high level of respiratory support required, and the difficulties encountered in ventilating him, were thought to be a result of bronchopulmonary dysplasia.

The mechanism of pulmonary hypoplasia remains unclear, but we have demonstrated that oligohydramnios per se is not always associated with low amniotic pressure. However, oligohydramnios, regardless of cause, is associated with respiratory problems in the neonatal period. Clinicians therefore need to look beyond amniotic pressure for the cause of pulmonary hypoplasia.

Pam Johnson, MBBS, and Darryl J. Maxwell, MBBS

Fetal Medicine Unit, Department of Obstetrics, Guy's Hospital, London, England SE1 9RT

Reply

To the Editors: We thank Drs. Johnson and Maxwell for their interest in our hypothesis on the pathogenesis of pulmonary hypoplasia. On the basis of three observations, they claim that oligohydramnios is not always associated with low amniotic pressure. This does not surprise us. In our recent series,[1] although all 24 cases of severe oligohydramnios (deepest pool <0.5 cm) had amniotic fluid pressure below the mean for gestational age, 16 were within the reference range. Indeed, our latest observations (unpublished) indicate that amniotic pressure in 37 cases of severe oligohydramnios is approximately 2 SDs lower (mean Z score = −2.04; 95% confidence intervals = −1.64 to −2.44; $p < 0.0001$) than the mean for gestational age in 117 pregnancies with normal amniotic fluid volume. Amniotic pressure in severe oligohydramnios caused by ruptured membranes ($n = 6$) was not as low as in those with intact membranes, but was nevertheless significantly lower than in controls (mean Z score = −1.09, 95% confidence intervals = −0.46 to −1.72; p 0.019).

Unfortunately, Drs. Johnson and Maxwell do not specify their criteria used to define olighydramnios. This is crucial since pressure does not seem to be reduced in cases of mild or moderate oligohydramnios.

Animal studies suggest that the mechanism of pulmonary hypoplasia in oligohydramnios is failure of retention of lung liquid within the developing airways.[2,3] Our observation of low amniotic pressure in oligohydramnios indicates that external compression is an unlikely cause for this loss of lung liquid. Instead we have hypothesized that an increase in the alveolar-amniotic gradient might be responsible.

The correspondents dismiss our hypothesis on the basis of finding "normal" amniotic pressure in a series of three pregnancies with oligohydramnios, without providing any evidence that these fetuses had pulmonary hypoplasia.

The validity of our hypothesis will be more appropriately tested in experimental animal studies currently under way.

Measurement of cardiac output by impedance technique

To the Editors: Masaki et al. have reported their experience in pregnancy with a new model of the Noninvasive Continuous Cardiac Output Monitor, model 3 (NCCOM-3), a device that measures cardiac output by impedance technique (Masaki DI, Greenspoon JS, Ouzounian JG. Measurement of cardiac output in pregnancy by thoracic electrical bioimpedance and thermodilution. AM J OBSTET GYNECOL 1989;161:680-4). The statistical analysis of the data and the interpretation of their results raise concerns.

The authors state that they used the method of Bland and Altman to assess agreement between methods. Their Fig. 2 is cited as an example of that method. This is a simple plot of one measure against the other, from

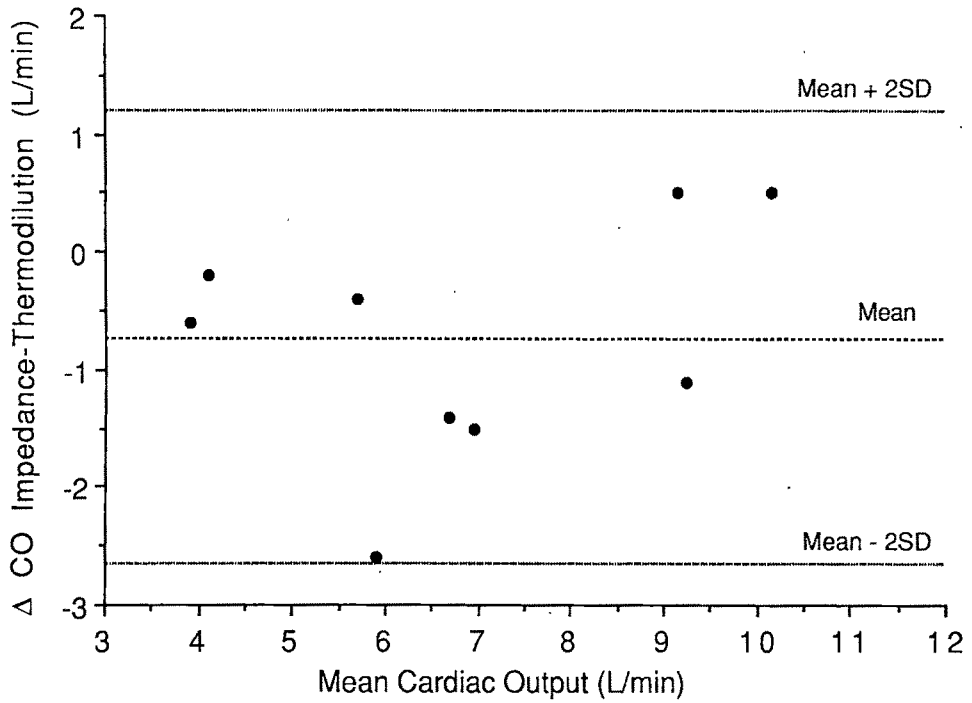

Fig. 1. Plotted data of Masaki et al.

which, according to Bland and Altman, "it will be difficult to assess between-method differences." We could find no other evidence that the Bland-Altman analysis was performed. To use the Bland-Altman method the mean of two measurements is plotted against the difference. Data from the study of Masaki et al. are plotted in Fig. 1. Reference lines of mean difference between measurements and 2 standard deviation confidence intervals have been included for comparison.

This method of analysis reveals two important points. First, impedance underestimates cardiac output in pregnancy. The mean difference in measurements is −0.73 L/min. Second, the confidence intervals are not small. The combination of these weaknesses places the lower confidence limit 2.7 L/min below what would have been obtained by thermodilution.

The discussion of the article fails to recognize the underestimation of cardiac output by impedance. Although the slope of their regression line is 1.04, the intercept is −1.03. Therefore the regression line parallels the line of identity with measurements by impedance being 1 L/min below those by thermodilution. The mean of measurements made by thermodilution is 7.24 ± 2.1. By impedance, the mean is 6.5 ± 2.5. The means are significantly different at $p = 0.05$ (paired t test). This shortcoming of the impedance technique has been previously demonstrated by the study of Atkins et al. in which cardiac output was not found to be elevated throughout most of pregnancy. The sources of potential errors have been reviewed by de Swiet and Talbert.[3] The new edition of the NCCOM-3 does not seem to overcome all of these problems.

The authors also have not discussed the large underestimations of cardiac output in three patients. In patient 4 the cardiac output was underestimated by 19.8%; in patient 5, by 19.1%; and patient 9, by 35.6%. These differences are large enough to be of clinical significance. Two of these patients had severe preeclampsia. We have previously reported similar large underestimations of cardiac output by impedance technique in this population.[4] In the patients we described, the errors in measurement of cardiac output were associated with very low, "subphysiologic," measurements of maximum $(dZ/dt)_{max}$ (the maximum rate of impedance change), one of the parameters in the Sramek-Bernstein equation. This is the same problem that makes measurement of cardiac output in patients with septic shock inaccurate.[5] I suspect that the patients described by Masaki et al. also had a low $(dZ/dt)_{max}$ value. Abnormalities in this parameter may indicate patients in whom measurement of cardiac output by impedance is inappropriate.

Finally, the authors have chosen to remove two patients from the study retrospectively because their medical conditions are ones in which the method does not work well. These determinations must be made prospectively before evaluating the data. Retrospective exclusion of subjects introduces substantial bias into the study.

Measurement of cardiac output by impedance technique in pregnancy must be done with an understanding of the limitations of the technique. First, it underestimates cardiac output in pregnancy. This difference is of importance when nonpregnant and pregnant women are compared. Second, there may be large un-

derestimations in cardiac output of patients with preeclampsia. These errors may provide misleading information about the hemodynamics of the disease and may prompt the physician to make errors in treatment of individual patients. In its present state of development, impedance technique of measuring cardiac output is not reliable in pregnancies complicated by preeclampsia.

Ultrasonography's role in detection of intrauterine synechiae

To the Editors: After reading the article "Intrauterine adhesions: Hysteroscopic diagnosis, classification, treatment, and reproductive outcome" by Valle and Sciarra (Am J Obstet Gynecol 1988;158:1459-70) I performed a level II ultrasonographic examination associated with genetic amniocentesis in a patient at 16 weeks' gestation. She had undergone postmiscarriage dilatation and curettage 10 years ago. Complete amenorrhea was relieved by hysteroscopy at that time. Ultrasonography at the time of genetic amniocentesis showed several uterine synechiae.

That pregnancy prompts me to remark on another patient in whom there had been a history of previous uterine surgery because of myoma. Ultrasonography at 16 weeks' gestation showed a uterine synechia. At 38 weeks' gestation the patient had a persistent breech presentation with the uterine synechia truly tethering the anterior uterine wall to the posterior uterine wall. The synechia was very low in the uterine cavity. Delivery was by elective cesarean section.

My question is to other obstetrician-ultrasonologists involved in ultrasonographic evaluation of the uterus in similar situations of patients who have undergone previous uterine surgery. Have they also seen instances in which uterine synechiae have had significant effects on obstetric management when the synechiae were visualized at the time of an ultrasonographic examination in the second trimester?

Is it reasonable to recommend ultrasonographic evaluation routinely early in the second trimester in patients who have had intrauterine surgery and/or intrauterine adhesion therapy?

John D. Stephens, MD
California Prenatal Diagnosis Institute, 1390 S. Winchester Blvd., San Jose, CA 95128

Addendum

Regarding concerns about intrauterine "shelves" in pregnancy, see the article from which the following is quoted (Brown DL, Felker RE, Emerson DS. Intrauterine shelves in pregnancy: sonographic observations. Am J Roentgenol 1989;153:821-4). "The patients had a history of dilatation and curettage or cesarean delivery, which predisposes the patient to formation of synechiae. This experience suggests that when a shelf of tissue where the free edge is present within the pregnant uterus, there should be no concern for the development of amniotic band syndrome as long as there is a complete sonographic survey of the fetus which reveals no abnormalities." There are other obstetric management implications above and beyond those regarding fetal development that need to be addressed and that I hope I have outlined here.

Reply

To the Editors: Little experience exists on the use of ultrasound to detect intrauterine adhesions either during pregnancy or in the nonpregnant uterus. With the rapid improvement in ultrasound technology, particularly with vaginal transducers, ultrasonography is being used with increasing frequency to evaluate the uterine cavity, with special interest in the assessment of endometrial thickness during various phases of the menstrual cycle.[1] In addition, leiomyomas, endometrial polyps, and malignant growths with myometrial invasion have been clearly seen.[2] Uterine wall defects related to previous surgery, particularly cesarean section scars, have also been evaluated ultrasonographically.[3]

Although hysterosalpingography and hysteroscopy are the best methods available today to accurately diagnose intrauterine adhesions, ultrasonography has been suggested as a method to detect this condition in nonpregnant women.[4] Because it is noninvasive, ultrasonography is an appealing method of evaluation, particularly in patients who are symptom-free but have a history of postpartum or postabortal curettage or other intrauterine surgery. Thus ultrasonic evaluation may eventually screen those patients likely to benefit from hysterosalpingography or hysteroscopy with precise diagnostic methods also permitting treatment of intrauterine adhesions. However, before ultrasound is used as a screening tool, its sensitivity, specificity, and predictive value should be determined by extensive clinical evaluation.

In the pregnant woman, ultrasonographic examination may become the method of choice to evaluate intrauterine pathology. This approach may be most applicable to patients who attempt pregnancy after lysis of intrauterine adhesions, but who have not had the benefit of a subsequent evaluation by hysterosalpingography or hysteroscopy. As suggested by Dr. Stephens, ultrasonography may be valuable in patients who become pregnant after therapy for extensive moderate to severe intrauterine adhesions, inasmuch as these patients may achieve pregnancy despite residual adhesions. Once pregnancy has been established, treatment of intrauterine adhesions is usually not possible; however, the ultrasonographic detection of adhesions during early pregnancy may serve as a warning to the clinician for closer obstetric surveillance. Further experience must be prospectively accumulated in such patients before ultrasound can be generally recommended.

We appreciate Dr. Stephens' interest in our article and encourage him to continue his ultrasonographic observations on intrauterine adhesions in both the nonpregnant uterus and during pregnancy.

Let our eminent medical authorities guide you through major new clinical advances

Introducing the

Year Book of Infertility®

This time-saving guide book makes it easy for you to keep current in your field. Each volume represents the year's most significant developments as reported in more than 800 journals and periodicals published worldwide. These selections are condensed to roughly a page in length, so you get all essential facts at a glance.

More importantly, the distinguished physician editors provide thoughtful, probing commentaries that explore the significance of each article while evaluating its practical implications for day-to-day practice.

Save hours of reading and research time and get expert guidance with this invaluable reference!

These books are published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days and returned for full credit. Year Book will remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

• Gynecologic Oncologist • Reproductive Endocrinologist • Clinical Geneticist

The Baystate Medical Center is the major provider of tertiary care in Western Massachusetts. It has recently expanded its resources through its designation as the Western Campus for Tufts University Medical School. In response, the Department of Obstetrics and Gynecology is expanding its full time faculty group.

The Department has over six thousand deliveries and three thousand operative procedures. Our staff consists of forty-five community based physicians, five certified nurse midwives, and eleven full time faculty in the fields of Maternal-Fetal Medicine, Reproductive Endocrinology, Gynecologic Oncology and Primary Care. The Department has a major commitment to Student Education and has an independent Resident Education Program with twenty residents. Excellent opportunities exist for basic and clinical investigation in many areas.

Baystate Medical Center offers a salary and academic rank commensurate with experience. The Department also has a practice plan. Send Curriculum Vitae or contact:

Laurence E. Lundy, MD, Chairman, Obstetrics and Gynecology
John Powell, MD, Chief, Gynecologic Oncology
Patrick O'Grady, MD, Chief, Maternal Fetal Medicine
Halina Wiczyk, MD, Chief, Reproductive Endocrinology

BOSTON UNIVERSITY UPDATE IN OBSTETRICS AND GYNECOLOGY–1990

Course Directors
Leonard J. Cibley, M.D.
Laurence J. Cibley, M.D.

A distinguished faculty will emphasize controversial topics and management of patients in broad areas of obstetrical and gynecological practice. This program should prove of interest to the practicing obstetrician-gynecologist, resident-in-training, as well as to the nurse-midwife and nurse practitioner.

November 5-7, 1990
Ritz-Carlton Hotel
Boston, Massachusetts

For further information, contact: Dept. of Continuing Medical Education, Boston University School of Medicine, 80 E. Concord St., Boston, MA 02118, (617) 638-4605.

BRIGHAM AND WOMEN'S HOSPITAL

Obstetrician/Gynecologist

The Brigham and Women's Hospital, a major teaching hospital of Harvard Medical School, seeks several obstetrician/gynecologists to join a busy full-time faculty group practice in general obstetrics and gynecology. The practice is located in a private setting near the hospital.

Applicants should be Board-certified/eligible.

Academic appointment at Harvard Medical School will be granted.

Offers competitive economic package and generous fringe benefits.

Commitment to clinical care and teaching are essential.

Send inquiry and curriculum vitae to:

Kenneth J. Ryan, M..D., Chairman
Department of Obstetrics and Gynecology
Brigham and Women's Hospital
75 Francis Street, ASB1-3-073
Boston, Massachusetts 02115

The Brigham and Women's Hospital is an affirmative action, equal opportunity employer.

MATERNAL FETAL MEDICINE SPECIALIST

BROOKDALE HOSPITAL

The Division of Maternal Fetal Medicine in the Department of Obstetrics and Gynecology is seeking additional faculty.

Excellent clinical and research opportunities exist with 5,000 obstetrical deliveries annually, a high proportion of which are high risk. A Level III nursery with a 42 bed Neonatal Intensive Care Unit is supervised by 3 full time neonatologists.

The residency is independent and fully approved and appropriate faculty appointment at SUNY-HSC, Brooklyn is available. Competitive salary and benefits package including malpractice insurance is offered. Income supplementation from a large consultation base exists and private practice opportunity available if desired.

Send CV or Contact: Richard J. Calame, M.D.,
Director Obstetrics-Gynecology

The Osler Institute
Obstetrics and Gynecology Review Course
October 22-27, 1990 — Omaha
November 26-December 1, 1990 — Chicago
Now, your course with case-list reviews and mock oral exams
Sponsored by the Osler Institute and Penn State

OBJECTIVES
- Increase basic knowledge and clinical skills in ob-gyn.
- Assist residents and fellows to organize study.
- Prepare board candidates to pass board examinations
- Provide practicing gynecologists with an update

METHODS
- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

*"Accommodations were comfortable...."**

GOALS AND LOCATION: This course for residents and practicing gynecologists is a comprehensive review and update offered in the spring and fall. The fall course is more clinically oriented. Home study questions are sent upon registration. Your best value is to repeat the course for half price immediately before exams. The October course will be at the Ramada Hotel Central Omaha, 7007 Grover Street, Omaha, Nebraska. Rates will be $69 single — $74 double. The November course will be at the Hilton Inn, 3003 Corporate West Drive, Lisle, Illinois. Rates will be $70 single — $90 double.

*"...and those little extras...."**

LOWEST AIR FARES: Please call toll-free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

CATEGORY 1 C.M.E. AND FEES:
- Penn State designates this continuing medical education activity for **60 credit hours in Category 1** of the Physician's Recognition Award of the American Medical Association.
- This program has been approved for **60 cognates, Formal Learning,** by The American College of Obstetricians and Gynecologists.
- Practicing Gynecologists: $720
- Residents and Fellows: $480
- Repeating course within 3 years: $360
- Case-list reviews and mock oral exams (half hour sessions) $ 70
- Optional extra day Dec. 2 (more questions, answers and pathology lab): $150
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- A deposit of $50 will reserve your position.

*"...home study material was extremely helpful."**

CANCELLATIONS: Refunds subject to $50 fee, will be made until the seminar begins.

*"...remarkably complete and pleasant."**

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets Spectacular!

norethindrone/ethinyl estradiol

white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet ins 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethe and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

RTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information ed with the product and therefore should not be used as the basis for prescribing the product. ummary was prepared by deleting from the complete prescribing information certain text, tables ferences. The physician should be thoroughly familiar with the complete prescribing information prescribing the product.

TIONS AND USAGE: PREVENTION OF PREGNANCY.

TRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following ons: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlethromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected oma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependeoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice ior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

rette smoking increases the risk of serious cardiovascular side effects from oral contracepuse. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and uite marked in women over 35 years of age. Women who use oral contraceptives should be ngly advised not to smoke.

of oral contraceptives is associated with increased risks of several serious conditions including f infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the ous morbidity or mortality is very small in healthy women without underlying risk factors. The idity and mortality increases significantly in the presence of other underlying risk factors such sion, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives miliar with the following information relating to these risks. The information contained in this ry is principally based on studies carried out in patients who used oral contraceptives with ulations of estrogens and progestogens than those in common use today. The effect of long f the oral contraceptives with lower formulations of both estrogens and progestogens remains ermined. Throughout this brief summary epidemiological studies reported are of two types: ective or case control studies and prospective or cohort studies. Case control studies provide a re of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contrae users to that among nonusers. The relative risk does not provide information on the actual clinical ence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in cidence of disease between oral contraceptive users and nonusers. The attributable risk does proformation about the actual occurrence of a disease in the population. For further information, the is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER LAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been iated with oral contraceptive use. This risk is primarily in smokers or women with other underlying ictors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and tes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two . The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has shown to contribute substantially to the incidence of myocardial infarctions in women in their hirties or older with smoking accounting for the majority of excess cases. Mortality rates associated circulatory disease have been shown to increase substantially in smokers, especially in those 35 . of age and older among women who use oral contraceptives. Oral contraceptives may compound the ts of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In cular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase d pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been iated with an increased risk of heart disease. Oral contraceptives must be used with caution in ne with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboemic and thrombotic disease associated with the use of oral contraceptives is well established. Case studies have found the relative risk of users compared to non-users to be 3 for the first episode of icial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for n with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the lative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative boembolic complications has been reported with the use of oral contraceptives. The relative risk of s thrombosis in women who have predisposing conditions is twice that of women without such al conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and ng and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events mbotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), pertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonrs who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for rs who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hyperon. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from ontraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estroncrease HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved n doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. vity and amount of both hormones should be considered in the choice of an oral contraceptive. ing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For particular estrogen/progestogen combination, the dosage regimen prescribed should be one which ains the least amount of estrogen and progestogen that is compatible with a low failure rate and the of the individual patient. New acceptors of oral contraceptive agents should be started on preparas containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two s which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a in the United States, the risk of developing myocardial infarction after discontinuing oral contracepersists for at least 9 years for women 40-49 years who had used oral contraceptives for five or e years, but this increased risk was not demonstrated in other age groups. In another study in Great the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation contraceptives, although excess risk was very small. However, both studies were performed with ntraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF LITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have ed the mortality rate associated with different methods of contraception at different ages. These s include the combined risk of death associated with contraceptive methods plus the risk attribupregnancy in the event of method failure. Each method of contraception has its specific benefits s. The study concluded that with the exception of oral contraceptive users 35 and older who smoke nd older who do not smoke, mortality associated with all methods of birth control is low and at associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who contraceptives have a significant increase in mortality higher than those using other methods of ntrol. These facts must be weighed in conjunction with failure rates for other methods and the risk ed with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous ological studies have been performed on the incidence of breast, endometrial, ovarian and cervical n women using oral contraceptives. While there are conflicting reports most studies suggest that oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. studies have reported an increased relative risk of developing breast cancer, particularly at a er age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids, however free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 9/89

ORTHO PHARMACEUTICAL CORPORATION
Raritan, NJ 08869-0602

ORTHO

Spectacular!
†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.
Please see complete Prescribing Information, a brief summary of which appears on the preceding page.
